Peptide chain release factors are soluble proteins that participate in the stop codon-dependent termination of polypeptide biosynthesis. In Escherichia coli, two release factors are necessary for peptide chain termination: release factor 1 (RF1) specifies UAGand UAA-dependent termination whereas release factor 2 (RF2) specifies UGA- and UAA-dependent termination1. Release factors are found in low concentrations relative to other translation factors², suggesting that their expression is tightly regulated and, accordingly, making the study of their structure-function relationship difficult. RF1 and RF2 exhibit significant sequence homology, probably reflecting their similar functions and perhaps a common evolutionary origin³. DNA and peptide sequencing have suggested the existence of a unique mechanism for the autogenous regulation of RF2 in which an in-frame UGA stop codon requires an obligatory +1 frameshift within the coding region of the RF2 gene. In this report we present in vitro experimental results consistent with the autogenous regulation of RF2. Additionally, we used RF2-lacZ gene fusions to demonstrate that autogenous regulation occurs, at least in part, by premature termination at the in-frame stop codon. since deletion of this stop codon leads to overproduction of the RF2-LacZ fusion protein. Frameshifting at this premature termination codon occurs at the remarkably high rate of 50%.

DNA sequencing demonstrated that the RF2 gene contains a UGA (opal) stop codon in-frame with the initiator methionine codon at codon position 26. Peptide sequencing of the amino terminus of RF2 confirmed that a +1 frameshift must occur at this position for the complete translation of intact RF23. Since RF2 uniquely recognizes opal stop codons⁴, RF2 may autoregulate when present in excess by prematurely terminating its own synthesis at codon 26.

To test this hypothesis we have used an in vitro coupled transcription/translation system to determine whether excess RF2 protein can suppress the translation of plasmid-encoded RF2. This system has been used to demonstrate autogenous translational regulation for a number of ribosomal protein operons⁵. Figure 1 shows the result of adding varying amounts of purified RF2 to the reaction mixture. Using the plasmidencoded β -lactamase as an internal standard it can be seen that RF2 production is reduced by increasing concentrations of added RF2. The addition of purified RF1 has no measurable effect (results are summarized in Fig. 2), and conversely the addition of RF2 has no measurable effect on RF1 synthesis (data not shown). We conclude that, at least in vitro, RF2 18 regulated at the translational level by its own gene product.

To determine whether this in-frame stop codon is the actual regulatory mechanism, and to measure the rate of frameshifting

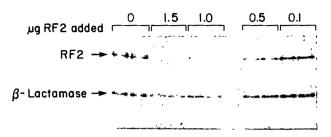

Fig. 1 In vitro autogenous regulation of RF2. A coupled transcription/translation system (Amersham) is used to demonstrate autogenous regulation of RF2. To a 30-µl reaction mixture containing ³⁵S-methionine, the indicated amount of purified RF2 protein ¹⁵ was added and the reaction started by the addition of 1 µg pRF2-1. The reaction was incubated at 37 °C for 30 min, followed by a 15-min chase with cold methionine, and the reaction products were displayed on a 12% SDS-polyacrylamide gel. The overall efficiency of the reaction is somewhat inhibited by the addition of RF2. Each reaction was performed in duplicate, and the complete experiment performed three times.

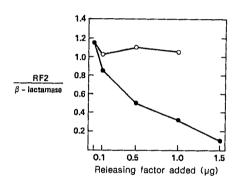

Fig. 2 A summary of the *in vitro* translation data for RF1 (O) and RF2 (\bullet). Band intensity was measured with a Helena Laboratories Auto-scanner densitometer and the intensity plotted as a ratio of RF2 to β -lactamase. The effect of purified RF1 protein was assessed as described in Fig. 1 legend for RF2, and plotted similarly. A representative experiment is depicted in the graph.

at this stop codon, RF2-lacZ gene fusions were constructed both with and without codon 26. It was assumed that these fusion proteins would be inactive for release factor activities and thus would not contribute to their own regulation. The construction of the gene fusions is shown diagrammatically in Fig. 3. Briefly, DNA restriction fragments containing 300-400 base pairs (bp) of 5' flanking sequence and either the first 12 codons (pEAB-1) or 67 codons (pEAB-2) of RF2 were inserted into a restriction site polylinker in the 5' coding region of the lacZ gene encoded on plasmid p9AB1. The lacZ promoter was subsequently removed by Bal31 digestion, and production of a fusion protein was confirmed by immunoprecipitation of 35S-methioninelabelled protein using anti-RF2 antibodies (Fig. 4). Only the pEAB-2 fusion protein is immunoprecipitable with anti-RF2 antibodies; presumably the pEAB-1 product lacks a sufficient RF2 sequence to be recognized by the anti-RF2 antibodies.

Bacteria harbouring these gene fusions were assayed for β -galactosidase activity, and the results are shown in Table 1. Several conclusions can be drawn from these results: first, since a high-level activity is seen with the gene fusion lacking codon 26, we conclude that the stop codon may be the only means by which RF2 expression is regulated, although we cannot exclude the possibility of an as yet undescribed 5' sequence, or sequences between codon 12 and 25, being involved in RF2 regulation.

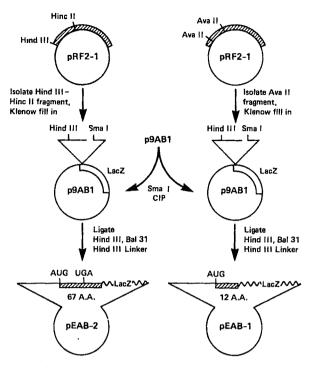

Fig. 3 The strategy for constructing RF2-lacZ fusion genes. The plasmid pRF2-1 contains the entire RF2 gene with 400 bp of 5' flanking DNA. Two DNA fragments containing the RF2 promoter. the initiating AUG, and either 12 codons or 67 codons of the coding region were isolated by restriction enzyme digestion and low melting agarose gel electrophoresis. Both fragments were made blunt-ended with the Klenow fragment of E. coli pol I, and ligated into SmaI-cut and dephosphorylated p9AB1. This plasmid contains the entire coding region of lacZ with a polylinker inserted in the amino-terminal end, and confers ampicillin resistance (provided by Bob Weiss, University of Utah). After ligation, the hybrid plasmid was redigested at a 5' flanking HindIII site, the adjacent lac promoter removed by Bal31 digestion, and a HindIII linker inserted to assess the size of the deletion. Plasmids containing an equivalent amount of 5' flanking DNA from the RF2 gene were selected for further study. The final plasmids are indicated at the bottom; pEAB-1 lacks the frameshift region, while pEAB-2 contains it.

This high level of activity also indicates that the RF2 gene contains a strong promoter, as underscored by the threefold greater activity of pEAB-1 over the parent plasmid activity. Second, by comparing the β -galactosidase activity of each RF2-LacZ fusion, a rate of frameshifting across the opal stop codon can be determined. Since pEAB-2 exhibits 50% of the β -galactosidase activity of pEAB-1, in the presence of normal levels of endogenous RF2 the ribosome can be assumed to frameshift at this rate. Thus, without a compensatory suppression of translation by excess RF2, the region around the in-frame stop codon permits a remarkably high level of frameshifting.

	Table 1	High-efficiency frameshifting
Plasmid	>	β-Galactosidase activity
pEAB-1		1.3×10^{4}
pEAB-2		6.4×10^{3}
p9AB1		4.5×10^{3}

 β -Galactosidase activity of RF2-LacZ fusion proteins. The assay was performed, and the units of activity calculated, according to Miller¹⁷. Bacteria were grown in minimal A medium supplemented with amino acids. The host strain is Su1675, a $recA^-$ derivative of CSH36 (Δ (lacpro), Laci⁻), provided by Bob Weiss. Plasmid copy number was determined by the method of Uhlin and Nordström¹⁸, and found to be essentially identical for all three plasmids.

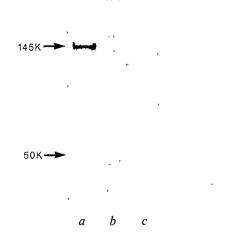

Fig. 4 Immunoprecipitation of RF2-LacZ fusion proteins. Exponentially growing E. coli, grown in minimal A medium¹⁷, was labelled with ³⁵S-methionine for 1 h and cell lysates made and immunoprecipitated with anti-RF2 antibodies, as described in Caskey et al. 16, except that the proteins were electrophoresed through an 8% polyacrylamide gel. a, Immunoprecipitated proteins from cells containing pEAB-2; b, from cells containing pEAB-1; c, from cells containing the parent lacZ plasmid p9AB-1. The band seen in a at a relative molecular mass of 145K (145,000) represents the RF2-LacZ fusion protein. The plasmid pEAB-1 fails to make an immunoprecipitable fusion protein, probably due to insufficient RF2 sequences being present, while the LacZ protein encoded on p9AB-1 fails to react with anti-RF2 antibodies. The bands seen at the 50 K position correspond to the endogenous RF2 protein.

Several factors influence the rate of frameshifting. Codon context has been shown to be important in determining the capacity of a particular codon to frameshift, with certain codons and their cognate transfer RNAs being inherently more 'shifty', and particular surrounding sequences having marked effects on the rate of frameshifting⁶. In certain circumstances the identity of the base found 3' to a shifty codon seems to play an important part in determining the rate of frameshifting at that codon, perhaps by allowing codon/anticodon mismatch and ribosome slippage⁷. Codon context has also been shown to effect the efficiency of nonsense suppression⁸, missense suppression⁹ and in vitro misreading of UGU codons¹⁰. Since previous examples of frameshifting were uniformly low-frequency events, factors involved in the recognition of stop codons by RF2 may be still another factor contributing to this high-efficiency frameshifting.

Natural frameshifting is involved in the expression of several prokaryotic and eukaryotic genes. Translation of the major coat protein of phage T7 (ref. 11), the gag-pol fusion protein of Rous sarcoma virus¹², and the analogous overlapping open reading frames of the yeast Ty912 transposable element¹³ involve an obligate frameshift event, although the exact position of the frameshift in these genes is unknown. In some of the above examples frameshifting may provide a mechanism for maintaining a fixed ratio of two separate proteins. For RF2 it seems that the frameshift is solely a means of regulating RF2 translation.

Elaborating the mechanism of frameshifting requires, as a first step, identifying the neighbouring sequences required for high-level frameshifting. Since RF2 exhibits a very high rate of frameshifting relative to artificial frameshift mutations¹⁴, RF2 may provide a unique model system for refining the rules of frameshifting, and for studying the mechanism of stop codon

A mouse locus at which transcription from both DNA strands produces mRNAs complementary at their 3' ends

Trevor Williams & Mike Fried

Department of Tumour Virus Genetics, Imperial Cancer Research Fund, Lincoln's Inn Fields, London WC2A 3PX, UK

The organization and large size of the mammalian cell genome allows spatial separation of different transcription units. In those cases where more than one species of messenger are synthesized from the same cellular DNA sequence, they have been found to be generated from transcription proceeding in the same direction. These mRNAs always share regions of homology and can differ from one another as a result of differential processing (splicing and/or polyadenylation) or alternative initiation 1-14. In contrast, complementary mRNAs transcribed from opposite strands of the same cellular DNA sequence have not previously been observed. Here we have identified a region of mouse DNA at which processed mRNAs from two adjacent convergent transcription units overlap by 133 base pairs (bp) at their 3'-untranslated ends. One of the transcription units appears to encode a second mRNA which does not contain this overlapping region. This represents the first description of the natural occurrence of processed mammalian cell mRNAs transcribed from opposite strands of the same DNA sequence. The implications of these complementary regions in normal gene regulation are discussed in the context of the finding that the artificial introduction into cells of DNA constructs synthesizing anti-sense RNAs complementary to regions of mRNA transcribed from a chromosomal gene, can inhibit the gene's activity, presumably by the formation of double-stranded RNA¹⁵⁻¹⁹.

We have used the 'expression selection' technique to isolate cellular DNA sequences with enhancer-like properties (expression sequences) by virtue of their ability to reactivate a test gene lacking its own 5' regulatory sequences^{20,21}. A 19kilobase (kb) EcoRI fragment of mouse cellular DNA containing the normal chromosomal location of the previously identified cellular expression sequence²⁰ has been cloned and characterized and found to encode a number of transcription units (T.W. and M.F., in preparation). The 746-bp PvuII/EcoRI subfragment (Fig. 1a) found at the right-hand end of the 19-kb clone is present as a single-copy sequence when used to probe Southern blots of mouse genomic DNA (Fig. 1b). In contrast, when this fragment is used to probe Northern blots of mouse poly(A)⁺ RNA, it hybridizes to two transcripts, of 1.2 and 3.0 kb (Fig. 1c). The presence of overlapping regions of the two

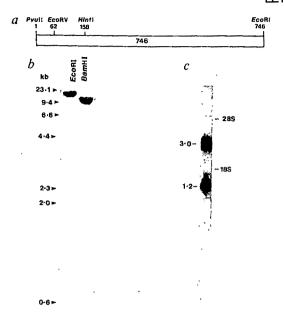

Fig. 1 Southern and Northern analysis of the 746-bp PvuII-EcoRI mouse cellular DNA fragment. a, Restriction map of the 746-bp PvuII-EcoRI fragment. This fragment was derived from one end of a 19-kb EcoRI clone (T.W. and M.F., in preparation) which contains a copy of a previously isolated mouse expression sequence²⁰, and which is subcloned into EcoRI/SmaI-cleaved pEMBL 8(+)³⁶. The PvuII, EcoRV, HinfI and EcoRI sites are indicated. b, Detection of a single copy of the 746-bp sequence in the mouse genome. A Southern blot of mouse genomic DNA digested with either EcoRI or BamHI was hybridized to the 746-bp probe. The numbers on the left show the sizes of the DNA markers (in kb). c, Northern blotting analysis of BALB/c TS-A-3T3 poly (A)⁺ RNA hybridized to the 746-bp fragment identifies two distinct mRNA species of 3.0 and 1.2 kb. On the right are shown the positions of the 28S and 18S ribosomal RNA markers.

Methods. For Southern blotting, 16 μg of BALB/c 3T3 DNA was digested with either EcoRI or BamHI, fractionated by electrophoresis on a 0.8% agarose gel, and transferred to nitrocellulose as described previously³⁷. For Northern blotting, total cellular RNA was prepared from BALB/c TS-A-3T3 cells²⁵ by the guanidinium/CsCl method³⁸ and poly(A) selected on oligo(dT)-cellulose; 5 μg of poly(A)⁺ RNA was fractionated on a 1% agarose/formaldehyde gel and transferred to nitrocellulose after partial alkaline hydrolysis³⁸. Hybridization conditions were identical for Northern and Southern blotting and both types of blot were washed to a stringency of 0.5× SSC at 68 °C essentially as described previously³⁷.

mRNAs was initially suggested by the finding that when uniformly labelled single-stranded probes specific for either strand of the 746-bp fragment were annealed to poly(A)+ RNA, both strands produced S₁-nuclease-resistant products, and the sum of these products was greater than 746 nucleotides. To more accurately localize the transcripts and determine the extent of their overlap, 3'S₁-nuclease mapping was performed using either a 746-nucleotide probe 3'-labelled at the EcoRI site or a 684nucleotide probe 3'-labelled at the EcoRV site at position 62 (Fig. 2a, probes A and B respectively). The probes were annealed to mouse RNA, and the S₁-nuclease-resistant products fractionated on polyacrylamide gels. Probe A, homologous to the top (A) strand, protects a 500-bp fragment (Fig. 2b, lane 3), locating a splice donor or polyadenylation site around nucleotide 242. Probe B, homologous to the bottom (B) strand, mainly protects a 310-bp fragment (Fig. 2c, lane 3), locating a splice donor or polyadenylation site around residue 372, but on the opposite strand. This indicates that the transcripts are derived from opposite strands and overlap by ~130 nucleotides.

To analyse the overlapping region in detail, complementary DNA clones corresponding to both transcripts were isolated

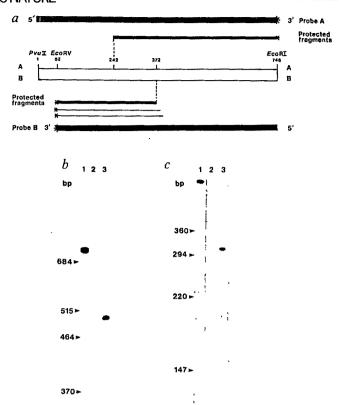

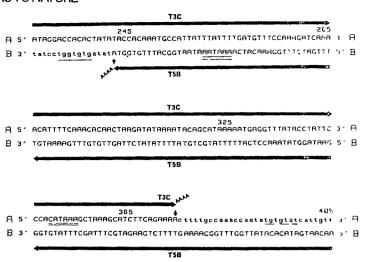

Fig. 2 Identification by 3' S₁ mapping of a region of mouse DNA where convergent transcription units overlap. a, Diagrammatic representation of the probes used for 3' S₁ mapping and the overlapping protected fragments. The open box represents the 746-bp fragment, with the A strand at the top and the B strand at the bottom. Nucleotide (nt) numbers above the DNA fragment are given from the PvuII site. The 746-nt probe A is illustrated by the solid box at the top, and is 3'-end-labelled at the EcoRI site (indicated by *). The 684-nt probe B, 3'-end-labelled at the EcoRV site, is similarly shown at the bottom. The major fragments protected in b and c are represented by the thick lines between the probes and the genomic sequence; the minor bands in c are represented similarly by thin lines. b, 3' S_1 mapping using the 746-nt probe A homologous to the A strand (see a). Lane 1, untreated probe; lane 2, probe plus 40 µg yeast RNA; lane 3, probe plus 40 µg BALB/c TS-A-3T3 total RNA. Marker DNA sizes are given on the left (in bp). c, 3' S₁ mapping using the 684-nt probe B homologous to the B strand (see a). Lane 1, untreated probe; lane 2, probe plus 40 μg yeast RNA; lane 3, probe plus 40 μg BALB/c TS-A-3T3 total RNA. Marker DNA sizes are given on the left (in bp).

Methods. The 746-bp fragment subcloned in pEMBL 8(+) was cleaved with either EcoRI (for probe A) or EcoRV (for probe B). Probe A was 3'-end-labelled at the EcoRI site using Klenow polymerase and ³²P-dATP and re-cut at the BamHI site present in the pEMBL 8(+) polylinker sequence. Probe B was 3'-end-labelled at the EcoRV site using T₄ DNA polymerase and ³²P-TTP and re-cut with EcoRI. Probes A and B were then prepared by electroelution after fractionation on 1% agarose gels. Procedures for RNA/DNA hybridization and S₁-nuclease digestion were essentially as described elsewhere³⁹. S₁-protected products were analysed by electrophoresis on 4% (b) or 6% (c) polyacrylamide gels containing 50% urea.

from a mouse cell cDNA library and sequenced. Figure 3 shows the relationship of the cDNAs T3C and T5B to the sequence of the 746-bp genomic fragment. The 3' 374 nucleotides of T3C (up to the start of the poly(A) tract) are homologous to the genomic sequence of the A strand from nucleotide 1 to 374. In addition, the 3' 505 nucleotides of T5B (up to the start of the poly(A) tract) are homologous to the genomic sequence of the B strand from position 746 to 242 (nucleotide numbers corre-

Fig. 3 A comparison of the genomic sequence of the 746-bp fragment with the cDNA sequences of T3C and T5B in the region of the overlap. The extent and orientation of the cDNAs are shown by the thick, solid arrowed lines above or below the sequence. Upper-case letters indicate sequences present in the processed poly(A)+ RNA; lower-case letters denote sequences 3' of the poly(A) addition sites. The vertical arrows indicate the last nucleotide of the genomic sequence which is homologous to the sequence of either T3C (A strand) or T5B (B strand). Beyond these positions the presence of poly(A) tracts in the cDNAs distinguishes them from the genomic sequence. The postulated poly(A) addition signals for both transcripts are indicated by double underlining. The postulated poly(A) addition signal for transcripts homologous to the B strand is the canonical AAUAAA⁴⁰, while that for transcripts homologous to the A strand, which may display microheterogeneity in the nucleotide used for poly(A) addition, is the much rarer CAUAAA⁴¹. The TG nucleotide blocks seen downstream of many poly(A) addition sites are underlined⁴²⁻⁴⁵. In contrast, the consensus sequence CAYUG, postulated to be important in the 3' processing of primary transcripts⁴⁶, is not seen in the vicinity of the poly(A) addition site for either transcript.

Methods. A cDNA library was constructed from BALB/c TS-A-3T3 poly(A)⁺ RNA as described elsewhere⁴⁷, with the following modifications: after second-strand synthesis the cDNA was repaired with T₄ DNA polymerase and ligated into λgt10 (ref. 48) after the addition of EcoRI linkers. cDNAs T3C and T5B were isolated on the basis of their homology to the 746-bp genomic fragment, and their EcoRI cDNA inserts were subcloned into pAT153. The sequence of the 746-bp fragment and the cDNA clones T3C and T5B in the region of the overlap was obtained for both strands by the dideoxy method⁴⁹ after appropriate restriction fragments had been subcloned into either M13mp18 or M13mp19 (ref. 50).

spond to the A strand sequence in Fig. 2). Thus, the two cDNAs analysed here are derived from mRNAs transcribed from opposite strands of the 746-bp genomic fragment (T3C from the B-strand template and T5B from the A-strand template) and overlap by 133 nucleotides at their 3' ends (Fig. 3), which is in agreement with the 3' S₁ mapping data presented in Fig. 2. The minor bands observed using probe B (Fig. 2c, lane 3) may be due to microheterogeneity in the choice of site for poly(A) addition²²⁻²⁴, in which case the exact extent of the overlap for processed mRNA would depend on which nucleotide was used for poly(A) addition for mRNAs homologous to the A strand (corresponding to cDNA T3C).

To determine which of the $poly(A)^+$ RNA species in Fig. 1c corresponded to which cDNA clone, a truncated fragment of T3C (deleted 3' to the HinfI site; see Fig. 4e) lacking the 3' overlapping sequences was used as a probe for Northern blotting and found to hybridize only to the 1.2-kb mRNA species (Fig. 4, compare a and b). When the cDNA clone RMC4, which is homologous to T5B but is truncated at its 3' end and contains only 18 bp of the overlapping sequences (Fig. 4c,e), was used as a probe for Northern blotting, it hybridized to 3.0-kb mRNA, but not to the 1.2-kb mRNA (Fig. 4c). Probe RMC4 also hybridized to a 2.4-kb mRNA (Fig. 4c,e), which was not visible if the 746-bp genomic clone was used as a probe (Fig. 4b). However, when used to probe Southern blots of mouse genomic DNA, clone RMC4 was found to represent single-copy sequence in the genome (data not shown); this suggests that, in addition to the transcripts homologous to the B strand which have been polyadenylated in the 746-bp fragment, typified by T5B (see Figs 3, 4e), there is an alternative shorter transcript terminating before the overlapping region of the 746-bp genomic sequence is reached (Fig. 4e). Further experiments will be necessary to determine whether the 2.4-kb poly(A)⁺ species is derived from this transcription unit by alternative 3' exon usage or alternative polyadenylation. We are presently cloning the mouse genomic DNA adjacent to the 746-bp fragment in order to further analyse the relationship of the 2.4-kb mRNA to the 3.0-kb mRNA.

The presence of the 1.2-kb and 3.0-kb mRNAs was assessed by Northern blotting in several normal and transformed clonal cell lines (Fig. 4d). No differences were detected in the ratios of the steady-state levels of the two mRNAs between normal BALB/c 3T3 cells and their transformed derivative BALB/c

TS-A-3T3 cells²⁵. However, the ratios of the steady-state levels of the two mRNAs in F9 (ref. 26) and MH15 (ref. 27) teratocarcinoma cells differed from those found in differentiated mouse cells (Fig. 4d). In the undifferentiated cells, the 3.0-kb mRNA appears to be down-regulated with respect to the 1.2-kb mRNA.

The function of the 1.2-, 2.4- and 3.0-kb mRNAs remains to be determined. However, in this context, the 5' end of the gene encoding the 1.2-kb mRNA maps in close proximity to the expression sequence²⁰ and displays a number of properties which are normally associated with housekeeping genes (T.W. and M.F., in preparation). The structures of the 3.0-kb and 2.4-kb mRNAs are presently being characterized.

The overlapping transcripts described here raise several interesting questions concerning the organization of genetic information and the control of gene expression. The mammalian genome characteristically contains individual genes separated by large regions of untranscribed DNA. In the present report we have identified a mouse genetic locus at which two processed poly(A)+ RNA species transcribed from opposite strands overlap by 133 nucleotides at their 3' ends. This finding implies a complex sequence organization in this region as the poly(A) addition signal for one transcript is contained in the exon sequence of the other, and vice versa. In addition, for those vertebrate genes in which it has been studied, transcription does not terminate at the poly(A) addition site but continues for some distance downstream. Therefore, the sequences that may be involved in the transcriptional termination or processing of one transcript are also probably encoded in the sequence giving rise to the transcript from the other strand, and vice versa. Therefore, it may be significant that the overlap is in the 3'-untranslated region of both mRNAs. Such overlapping transcripts have been identified previously in mammalian viruses, for example, the early and late mRNAs of polyoma virus overlap by 50 nucleotides and those of simian virus 40 by 87/88 nucleotides, although there is temporal control of the expression of these opposite strands2

In prokaryotes the formation of double-stranded RNA by the hybridization of complementary transcripts is important in the regulation of gene expression and replication. Such a mechanism has been shown to be responsible for the inhibition of translation of the *ompF* (ref. 29) and IS10 transposase³⁰ genes, and the control of replication of the plasmid ColE1 by inhibiting RNA

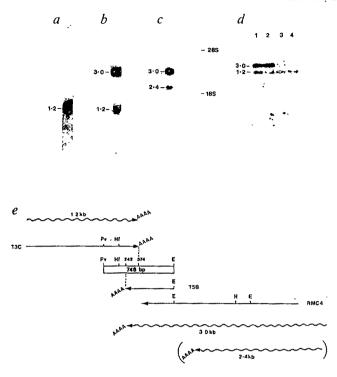

Fig. 4 Analysis of mRNAs homologous to the overlapping region. a, Northern blot analysis of BALB/c TS-A-3T3 poly(A)⁺ RNA to determine which mRNA is homologous to cDNA clone T3C (see e). A fragment of T3C lacking sequences 3' of the Hinf1 site (nucleotide 158 on the genomic sequence shown in e) and so missing the overlapping sequence, was used as a probe. b, Northern blot analysis of BALB/c TS-A-3T3 poly(A)+ RNA hybridized to the 746-bp fragment. c, Northern analysis of BALB/c TS-A-3T3 poly(A)+ RNA hybridized to cDNA RMC4 (see e) identifies mRNAs of 3.0 kb and 2.4 kb. cDNA RMC4 was isolated from a cDNA library derived from mouse mammary tumour virus-transformed mouse cells (given by R. Moore) on the basis of its homology to the 746-bp genomic fragment. RMC4 is truncated at its 3' end 115 bp before the poly(A) addition site and so lacks all but 18 bp of the overlapping sequences that would hybridize to the 1.2-kb mRNA. d, Northern blot analysis of mouse poly(A) RNA from differentiated cell lines (lane 1, BALB/c TS-A-3T3; lane 2, BALB/c 3T3) and undifferentiated teratocarcinoma cell lines (lane 3, MH15; lane 4, F9) hybridized to the 746-bp fragment. e, Organization of cDNA clones and transcripts in the vicinity of the 746-bp fragment. The 746-bp cellular DNA sequence is indicated by an open box. The straight lines represent the cDNA clones, with the arrows showing the direction of transcription and AAAA indicating the presence of a poly(A) tail. The dotted lines between the 746-bp fragment and T3C or T5B indicate the extent of the cDNAs with respect to the sequence of the genomic A strand; the last nucleotide of each cDNA is given above the 746-bp fragment (see Fig. 3). Wavy lines indicate the positions of the mRNAs, with their direction of transcription shown by arrows, and the poly(A) tails indicated by AAAA. The wavy line in parentheses represents the 2.4-kb mRNA which is related to the cDNA clone RMC4 but which terminates before the EcoRI site is reached (see c). The positions of relevant restriction enzyme sites are indicated: E, EcoRI; Pv, PvuII; H, HindIII; and Hf, HinfI. RNA preparation and Northern blotting procedures were identical to those described in Fig. 1 legend.

priming³¹⁻³³. In eukaryotes the introduction of anti-sense RNA, or vectors expressing anti-sense RNA, into cells has been used as a tool for the inhibition of gene product expression^{15,16}. In a cytoplasmic location, anti-sense RNAs which are complementary to the 5' sequence of a mRNA have been found to be more inhibitory than anti-sense RNAs complementary to the 3' sequence. This effect appears to be mediated by the ability of anti-sense RNAs to inhibit the translation of the specific mRNA

to which they are complementary 17,18. However, when anti-sense transcripts are expressed in a nuclear location, inhibition probably occurs via the formation of double-stranded RNA, which prevents the transport of sense transcripts from the nucleus; in this case, sequences complementary to the 3' portion of the sense transcript are as potent as those complementary to the 5' sequences 19. In addition, in Saccharomyces cerevisiae the CYC1 gene and an adjacent gene are convergently transcribed from opposite strands, but transcription termination signals located between the two genes normally ensure that transcripts from one gene do not read-through into the other gene and vice versa. The deletion of these termination signals generates overlapping convergent transcription from opposite strands and has a marked deleterious effect on the mRNA levels yielded from both transcription units34

Therefore, the two overlapping transcripts described here may display some novel mechanism of control of mammalian gene expression. First, if the overlapping transcripts were expressed at the same time, it might be expected that RNA polymerase complexes travelling in opposite directions along a DNA duplex might encounter a considerable degree of steric hindrance, especially as transcription probably continues past the poly(A) addition site³⁵. Second, although the abundance of the mRNAs is fairly low (<0.01% for each of the two mRNA species), the local concentration of the two opposite-strand transcripts in the vicinity of the 3'-ends of the transcription units might favour RNA duplex formation with concomitant inhibition of RNA processing and/or transport from the nucleus. Thus the two strands might be only rarely transcribed and their mRNAs very stable, or there might be some temporal or spatial control of expression such that their transcription occurs at different times in the cell cycle or from different alleles. Alternatively, coincident convergent transcription might be involved in controlling the expression of one or both of these transcripts. For example, it may be that when transcription of the 1.2-kb mRNA species is required, the shorter, non-overlapping 2.4-kb mRNA is generated from the opposite strand. Finally, an effect on the translation of either the 1.2-kb or the 3.0-kb mRNA by the overlap cannot be excluded. Further studies on the transcription of this mouse genomic locus may answer some of these questions.

We thank Drs P. Goodfellow, N. Jones, I. Kerr, P. Nurse and M. Parker for helpful discussions, and Mrs G. Briody and Mrs C. Middlemiss for typing the manuscript.

Overlapping transcription units in the dopa decarboxylase region of *Drosophila*

Charlotte A. Spencer, R. Daniel Gietz & Ross B. Hodgetts

Department of Genetics, University of Alberta, Edmonton, Alberta, Canada T6G 2E9

The many examples of overlap in the genes of various viruses and bacteria illustrate that the parsimonious utilization of the coding capacity of DNA is relatively common amongst prokaryotes (for review, see ref. 1). The recent discovery of a pupal cuticle gene within an intron of the completely unrelated Gart locus in Drosophila² shows that overlapping transcription units also exist in higher organisms. However, the prevalence of such phenomena is unknown. We report here a quite different situation of overlap between the 3' termini of a pair of convergent transcription units in another region of the Drosophila genome. This 88-base-pair (bp) genomic region encodes the 3' terminus of the messenger RNA for the enzyme dopa decarboxylase (Ddc) and, in opposite orientation, the 3' terminus of the adjacent gene whose function is unknown. An analysis of the temporal and spatial distribution of the two transcripts within the organism shows that high levels of both transcripts are never concordant. However, within the testes, where the 3' transcript is maximally expressed, low levels of Ddc transcript were detected. This result raises the possibility that a hybrid molecule involving the two transcripts forms in vivo or that transcription interference occurs, with concomitant regulatory implications.

Previous work has shown that the dopa decarboxylase region of Drosophila, as defined by the deficiency DF(2L)TW130 (ref. 3), contains a cluster of 18 genes, 14 of which appear to function in cuticle development and catecholamine metabolism⁴. Four genes, including Ddc, have been mapped within a 12-kilobase (kb) region and primary transcripts from these genes account for ~10.5 kb of the genomic DNA⁵. This tight clustering of genes has complicated our previous analysis of Ddc transcripts⁶, because the DNA probes we used in that study were found to encompass both Ddc and its 3'-adjacent transcription unit7. Strand-specific RNA probes revealed that the 3'-adjacent transcript originated on the opposite strand from that of the Ddc transcript and a hybridization of Northern blots to a series of nested single-stranded probes showed that the 3' termini of the Ddc gene and the adjacent gene apparently lie on opposite sides of the HpaI site shown in Fig. 1. However, subsequent analysis of the DNA sequence in this region showed that putative polyadenylation signals for the two genes are present on opposite sides of the HpaI site (see Fig. 1). This result suggested the possibility of a slight amount of overlap between the two transcripts in the vicinity of the HpaI site. We have now obtained complementary DNA clones for both Ddc and the 3'-flanking gene, and a comparison of their DNA sequences with the genomic DNA sequence confirms that an 88-bp overlap between the two 3' termini exists.

A cDNA library in λgt10 was made using poly(A)⁺ RNA from newly eclosed adults as described elsewhere8. Two clones each of Ddc and the 3'-flanking gene were chosen for further analysis. The inserts, which ranged in size from 1.1 to 2.0 kb, were re-cloned into M13mp19 and the ends of each fragment were sequenced (Fig. 2). Clones ACP, ACQ and ACR represented intact 3' termini, as revealed by tracts of oligo(dT) (or oligo(dA), depending on their orientation within the cloning vector) not found in the genomic sequence. The polyadenylation site of the 3'-adjacent gene was assigned unambiguously from the two cDNA clones of different length (ACQ and ACR); it is indicated by an asterisk beneath the genomic sequence in Fig. 2. A canonical polyadenylation signal sequence, 5'AATAAA3', lies 16 bases upstream of the terminal C residue (boxed in Fig. 2). The polyadenylation site for the Ddc gene (indicated by an asterisk above the genomic sequence in Fig. 2) could not be assigned unambiguously from the cDNA sequence because of

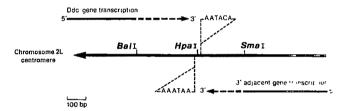

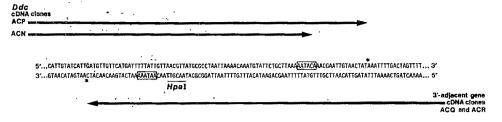

Fig. 1 Mapping the 3' termini of Ddc and the adjacent gene. The figure summarizes the results of our earlier work in which strandspecific RNA probes were used in a Northern analysis of poly(A) RNA from the mature larval and young adult stages of Drosophila7. Single-stranded Ddc-specific probes indicated that transcription of this gene terminated in the Ball-Hpal interval, while probes specific for the flanking gene indicated that its transcripts terminated in the HpaI-SmaI interval. Possible polyadenylation signals, chosen on the basis of their similarity to the eukaryotic consensus sequence 5'AATAAA3' (see ref. 9), were obtained from genomic DNA sequence analysis. Their precise locations with respect to the HpaI site are shown in Fig. 2.

the uncertainty caused by a run of adenine residues in the genomic sequence. However, we believe the site chosen at the T residue in Fig. 2 is the most likely one, based on its similarity the eukaryotic polyadenylation addition sequence 5'...Py\(^1\)A...3' (ref. 9); a hexameric sequence (5'ATTACA3') which could control poly(A)+ addition at this residue lies 16 bases upstream of it. Although this sequence appears to be an inefficient signal for transcription termination¹⁰, the other possible hexamers 5'AACAA3' and 5'AATTAA3' lie 38 and 43 bases upstream, farther than any reported in the most recent review9.

The extent of overlap that we have found between the 3' termini of the poly(A)⁺ mRNAs may reflect an even greater overlap between the unprocessed, non-adenylated transcripts, assuming that transcription termination occurs in Drosophila 1 kb or farther downstream of the $poly(A)^+$ signal sequence, as is known to occur in other systems. The overlap also raises the intriguing possibility that a sense/anti-sense hybrid might exist in vivo, with regulatory implications for the expression of one

Fig. 2 Genomic DNA sequence in the region of overlap between the *Ddc* transcription unit and the 3'-flanking gene. The sequence of both strands of the genomic DNA was determined by the dideoxynucleotide method of Sanger¹⁵ and constitutes part of a 5-kb sequence including the entire *Ddc* gene⁸. Poly(A) signal sequences are boxed. Methods. Sequences of the cDNA

molecules near their 3' termini were obtained from single- or double-stranded templates in which the cDNA constructs were cloned into M13mp19. The cDNA libraries were prepared from poly(A)⁺ adult RNA as described elsewhere⁸. Ddc-specific clones were identified using a nick-translated HpaI genomic fragment which extends 3.6 kb upstream of the HpaI site shown in Fig. 1. Although this fragment actually includes the 3'-terminal 26 nucleotides of the flanking gene, the extent of homology between the probe and the 3' gene is insufficient to generate a stable hybrid under the conditions used. Clones of the 3'-flanking transcription unit were identified using the strand-specific probe 10 (ref. 7), which is homologous to the HpaI-SmaI interval shown in Fig. 1.

or both mRNAs. We therefore undertook analyses of the temporal and spatial distribution of Ddc transcripts and of the 3'-adjacent transcripts during the life cycle of Drosophila. Our earlier work indicates that the developmental expression of the two genes is quite different. Maximum levels of dopa decarboxylase occur in 18-h embryos, at each larval moult, at pupariation and at adult eclosion11. The 3'-adjacent transcript, however, is abundant only in adult stages and in 1-4-h embryos⁷. These data make it unlikely that the region of overlap between the two transcripts has biological significance during embryonic or larval life. However, both transcripts are present in adult flies (Fig. 3). Between 0 and 4 days, the level of mature Ddc transcript (the 2.0-kb species^{6,12}) decreases, although substantial amounts of the 3.0-kb Ddc species are still present (Fig. 3a). High levels of the 3'-adjacent transcript are present in both newly eclosed and 4-day-old adults and an obvious sexual dimorphism in both the amount and size distribution of this transcript is apparent (Fig. 3b).

To further define the distribution of the two transcripts within adults, we prepared RNAs from several dissected fractions of newly eclosed adults and quantitated the two transcripts by dot hybridization (Fig. 4). Control experiments (not shown) indi-

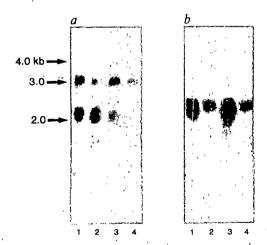

Fig. 3 Northern analysis of transcript levels in male and female adults. Duplicate samples of poly(A)⁺ RNA (5 μ g) were subjected to Northern analysis as described previously⁷. The autoradiogram in a shows the hybridization response to the *Ddc*-specific RNA probe 5 prepared by in vitro transcription of a 1.5-kb genomic fragment including \sim 600 bp from the 3' end of *Ddc*⁷. b, The response to probe 4 (ref. 7), transcribed from the opposite strand of the same genomic fragment and therefore complementary to transcripts of the 3'-adjacent gene. Lanes 1, newly eclosed male; 2, newly eclosed female; 3, 4-day-old adult male; 4, 4-day-old adult female.

cated no detectable hybridization to either of the strand-specific probes in purified ribosomal or $poly(A)^-$ cytoplasmic RNA from young adults. The pattern of Ddc expression in whole heads, thoraces and abdomens of both males and females (Fig. 4a) is consistent with a distribution of the enzyme in epidermal¹³ and neural tissue¹⁴. The higher concentration of Ddc transcripts in male abdomens (Fig. 4a, dot 7) than in female abdomens (a, dot 3) probably results from the contribution of testicular Ddc transcripts (a, dot 8) to the male abdominal sample. Longer exposures indicated a very low but detectable level of Ddc transcript in dissected ovaries (Fig. 4a, dot 4).

The pattern observed for the 3'-adjacent transcripts appears almost complementary to that of the *Ddc* transcripts (Fig. 4b): low, but detectable levels of the former transcript occur in both male and female heads and thoraces, and in female abdomens and ovaries. Clearly, though, the 3'-adjacent gene transcripts accumulate primarily in the testes (Fig. 4b, dot 8). A Northern analysis of total RNA samples from the dissected tissue samples confirmed that the male-specific size distribution of the 3'-adjacent gene transcripts (Fig. 3b) is also seen in the testes. Similarly, the female-specific size distribution (Fig. 3b) is identical to that contributed by ovaries and 2-h embryos (data not shown).

The data presented here, and our previous work⁷, indicate that high levels of the two overlapping transcripts are found only within young adults. However, the maximal steady-state levels of the two transcripts occur in different tissues. *Ddc* transcripts are confined primarily to the epidermis of males and females whereas transcripts of the 3'-adjacent gene accumulate primarily in the testes. The presence of low levels of *Ddc* transcript in the testes makes this the most likely place for formation

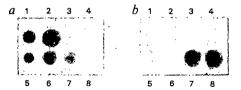

Fig. 4 Tissue distribution of transcripts of *Ddc* and the 3'-adjacent gene. RNA dot-blots were hybridized with: a, RNA probe 12, which is homologous to only RNA molecules transcribed from the 3'-flanking gene⁷; and b, RNA probe 5, which is homologous to only *Ddc* transcripts⁷. Total RNA was extracted as described previously from newly eclosed animals that had been dissected in D-20 medium¹⁷. Twelve animal equivalents were spotted in each case. RNAs in dots 1-4 were obtained from female samples, those in dots 5-8 from males. Dots 1, 5, heads; dots 2, 6, thoraces; dots 3, 7, abdomens; dots 4, 8, isolated gonads. The lengths of the two probes and their respective specific activities were similar, thus the intensities of the dots in a and b represent the relative steady-state levels of the two transcripts.

of a sense/anti-sense hybrid molecule containing both transcripts. However, confirmation of this possibility must await further detailed functional analysis of the 3'-adjacent transcription unit and in situ studies of the cell-specific distribution of both species of transcript. While this is only the second known example of overlapping genes in Drosophila, such arrangements in eukaryotes may be more common than previously supposed.

We thank Drs Larry Marsh and Ted Wright for sharing unpublished results. A studentship (C.A.S.) and a fellowship (R.D.G.) from the Alberta Heritage Fund for Medical Research are gratefully acknowledged. This research was supported by grant A6377 from NSERC (Canada).

The RNA required in the first step of chlorophyll biosynthesis is a chloroplast glutamate tRNA

Astrid Schön*, Guido Krupp, Simon Gought, Sandra Berry-Lowet, C. Gamini Kannangarat & Dieter Söll‡

Department of Molecular Biophysics and Biochemistry, Yale University, PO Box 6666, New Haven, Connecticut 06511, USA † Department of Physiology, Carlsberg Laboratory, Gamle Carlsberg Vej 10, 2500 Copenhagen Valby, Denmark

A molecule of chlorophyll is synthesized from eight molecules of δ -aminolevulinate (DALA), the universal precursor of porphyrins. The light-regulated conversion of glutamate to δ -aminolevulinate in the stroma of greening plastids involves the reduction of glutamate to glutamate-1-semialdehyde and its subsequent transamination¹⁻⁵. The components performing this conversion have been isolated from barley^{1,2} and Chlamydomonas⁵ and separated into three fractions by serial affinity chromatography on Blue Sepharose and haem-1,5 or chlorophyllin-Sepharose². The complete reaction can be performed in vitro in a reconstituted assay by combining all three fractions. An RNA is the essential component of the chlorophyllin-Sepharose-bound fraction^{2,3}. By nucleotide sequence analysis, we have now identified this RNA as a chloroplast glutamate acceptor RNA. Glutamate attached by an aminoacyl bond to the 3'-terminal adenosine of this RNA is a substrate for the enzyme(s) which perform the subsequent reactions. This reaction represents a novel role for transfer RNA: participation in the metabolic conversion of its cognate amino acid into another metabolite of low relative molecular mass which subsequently is not used in peptide bond synthesis.

The ultraviolet spectrum of the haem- or chlorophyllin-Sepharose-bound fraction showed the characteristics typical of

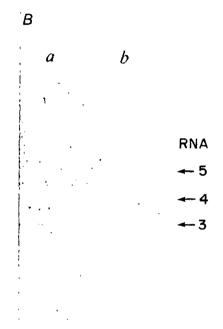

Fig. 1 Purification of RNADALA, A, HPLC fractionation. RNA was recovered from the chlorophyllin-Sepharose-bound fraction by phenol extraction, precipitated with ethanol and injected into 250×9-mm column packed with trioctylmethylammonium chloride-coated 5µ Hypersil ODS (refs 2, 37). Separation was achieved with a 4-h linear gradient from 0.5-2.3 M ammonium acetate (pH 5.1). Fractions 181-187 were pooled and the RNA was precipitated with ethanol. Glutamate acceptor activity and δ-aminolevulinate synthesis were determined as described elsewhere². B, Gel purification. For further purification, aliquots of the pooled HPLC fraction (5 µg dry RNA) were dissolved in 8 M urea containing 0.03% of tracking dyes and loaded into 10-mmwide slots of 15% polyacrylamide sequencing gels $(20 \times 40 \times$ 0.2 cm); electrophoresis was at 1,500 V until Sigma brilliant blue had reached the bottom of the gel8. Gels were stained with toluidine blue 0 and RNA was recovered as described previously³⁸. Lane a, RNA species present after HPLC fractionation; lane b, separation of partially purified RNAs (recovered from incompletely resolved RNA bands 3-5 in a less extensive electrophoresis). RNAs 1-3 were tested for their ability to function in δ -aminolevulinate biosynthesis (see Table 1).

nucleic acids. From these data and the fact that ribonuclease treatment of this fraction destroyed its ability to support δ aminolevulinate formation in the reconstitution assay, it was concluded that RNA is the active principle in the haem- or chlorophyllin-Sepharose-bound material^{2,3}. Phenol extraction of this material and HPLC fractionation led to the separation of three fractions of glutamate acceptor activity (Fig. 1A). Only the first species was able to support δ -aminolevulinate formation in the reconstitution assay (Fig. 1A). From this HPLC fraction

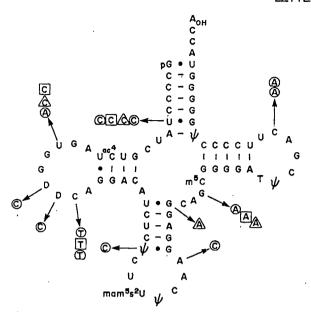

Fig. 2 Nucleotide sequence of RNADALA. The sequence was determined by base-specific enzymatic and chemical cleavage of the 5'- and 3'-end-labelled RNA6-9. Modified nucleotides were identified by the method of Stanley and Vassilenko⁶. Ambiguities due to the tight secondary structure and the lability of mam⁵s²U were resolved by mobility shift analysis11 of fragments generated either by complete digestion with RNase T₁ or by partial cleavage with aniline⁹. Arrows indicate differences in primary structure from chloroplast tRNA^{Glu} genes of the following species: Nicotiana tabacum¹⁹, squashed circle; Vicia faba²⁰ and Pisum sativum²¹, squares; spinach²², triangle; Euglena gracilis²³, round circle. The sequence is identical to a wheat (Triticum aestivum) tRNAGlu gene.

a homogeneous active RNA species, referred to as RNADALA, was purified by polyacrylamide gel electrophoresis (Fig. 1B, Table 1). Analysis of the nucleotide sequence of this RNA was complicated by the fact that it contained a chemically labile base and possessed an extremely stable secondary structure. Chemical and enzymatic sequence analysis of the 3'- and 5'-endlabelled RNA⁶⁻⁹, as well as fingerprinting of post-labelled RNA¹⁰, established the structure of a tRNA (Fig. 2). The labile base in the first position of the anticodon was identified as 5-methylaminomethyl-2-thiouridine (mam⁵s²U). This was established by co-migration of the [5'-³²P]-nucleoside monophosphate¹¹ with the authentic marker nucleotide prepared from Escherichia coli tRNA Glu₂ (refs 12, 13) in several thin layer chromatographic systems¹⁴⁻¹⁷ as well as by its sensitivity to cyanogen bromide12 and its behaviour in a mobility shift analysis 11. The nucleotide mam 5s 2U has previously been found exclusively in the tRNAs of prokaryotic organisms 18. Its occurrence in chloroplast tRNA supports the endosymbiont theory of the prokaryotic origin of organelles¹⁹. The anticodon sequence UUC (unmodified) suggests a glutamate tRNA, in agreement with its

amino-acid acceptor properties (Fig. 1).

Comparison with known tRNA^{Glu} gene sequences (no other chloroplast tRNA^{Glu} species have been sequenced to date) showed high homology to tRNAGiu genes from chloroplasts of higher plants²⁰⁻²⁵: the known wheat (Triticum aestivum) gene has a sequence identical to the barley RNADALA. The sequence from tobacco (Nicotiana tabacum) differs in only three bases, the sequences from broad bean (Vicia faba), pea (Pisum sativum) and spinach (Spinacea oleracea) differ in four positions, whereas the sequence from Euglena gracilis shows nine differences (Fig. 2). One distinctive feature of tRNA^{Glu} of chloroplast origin, the A53:A61 pair^{22,23} (the last base pair in the $T\psi C$ -stem), is also present in this tRNA. The RNA^{DALA} requires an intact 3'-terminal CCA end for its

ability to support δ -aminolevulinate formation. This was demon-

strated by inactivating the glutamate acceptor and δ aminolevulinate-synthesizing activity of the RNA by partial exonucleolytic digestion with snake venom phosphodiesterase and subsequent restoration by repair of the 3'-terminal CCA end with tRNA nucleotidyl transferase²⁶ (Table 1). The linkage between glutamate and RNA was identified as an authentic aminoacyl bond after labelling the 3'-end of the purified RNA with $[\alpha^{-32}P]$ ATP by use of nucleotidyl transferase and charging with 14C-glutamate using the Blue Sepharose-bound enzyme fraction. The terminal ¹⁴C-glutamyl-³²P-adenosine 5'-phosphate was recovered after cleavage with nuclease P₁ and identified by thin layer chromatography¹⁴, using as a marker ¹⁴C-glutamyladenosine 5'-phosphate derived from pure aminoacylated E. coli tRNAGlu2 (data not snown). These findings indicate that, as in aminoacyl-tRNA, the α -carboxyl group of glutamate is probably aminoacylated. However, we cannot rule out the possibility that amino-acid activation involves the y-carboxyl group.

The presence of an enzyme-associated RNA in the chloroplast led to questions of whether, in barley, RNADALA is encoded in the chloroplast DNA and whether the location of the gene is the same in widely different plant species. Although it is generally believed that organellar RNAs are encoded in the organellar DNA, RNA transport into the mitochondrion has also been described²⁷. Hybridization experiments were performed using genomic and chloroplast DNAs from various plant species, including unicellular algae. To allow comparisons with the available HindIII bank of the barley chloroplast genome²⁸, and because the sequence of RNA^{DALA} shows a unique HinfI restriction site in the T-loop region, HindIII and HinfI treatments were chosen for Southern hybridizations. To avoid artefacts

δ-Aminolevulinate synthesis was assayed in a mixture containing 0.5 mM ATP, 1 mM NADPH, 25 mM MgCl₂, 1 mM dithiothreitol (DTT), 0.3 M glycerol, 0.1 M Tricine-NaOH (pH 7.9), 0.25 mg Blue Sepharose-bound protein, 0.4 mg unbound protein and 2.5 µCi ¹⁴C-glutamate (275 ci mmol⁻¹; 330,000 c.p.m. pmol⁻¹) in a total volume of 0.5 ml. 10-50 µg RNA was used per assay. The conversion of glutamate to δ-aminolevulinate was determined as described elsewhere². For exonuclease inactivation of RNA, 100 µg of HPLC-purified RNA was incubated for 20 min at room temperature with $2\,\mu g$ snake venom phosphodiesterase in 50 mM Tris-HCl (pH 8), 10 mM MgCl₂. The material was then phenol extracted and ethanol precipitated. Reactivation was performed with 50 µg of this RNA in 0.4 ml, containing 25 µM ATP, 25 μM CTP, 10 mM MgCl₂, 8 mM DTT, 40 mM Tris-HCl (pH 8) and 62.5 µg (0.6 U) of tRNA nucleotidyl transferase. After incubation for 45 min at 37 °C, the RNA was phenol extracted, ethanol precipitated and assayed for reconstitution activity as described above, 3'-End labelling of the gel-purified active RNA species was performed with 5 µg RNA by scaling down these protocols and substituting [5'-32P]ATP (3,000 Ci mmol⁻¹, 36 pmol) for ATP.

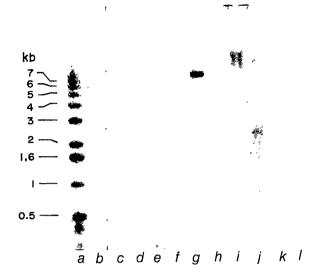

Fig. 3 Hybridization of RNA^{DALA} to genomic and chloroplast DNA. Restricted DNA $(1-2 \mu g)$ was separated on a 0.7% agarose gel and blotted onto nitrocellulose paper³⁹. Hybridization was performed in $6 \times SSC$, $3 \times Denhardt's$ solution and 0.1% sodium pyrophosphate for 1 h at 42 °C. Nonspecifically bound probe was removed by washing the filter with $2 \times SSC$ at 42 °C. The lanes contained: a, DNA size markers; b, barley genomic DNA; c, d, barley chloroplast DNA; e, f, tobacco genomic DNA; g, h, tobacco chloroplast DNA; i, j, Chlamydomonas reinardii genomic DNA; k, l, Chlamydomonas reinhardii chloroplast DNA. All samples were digested with HindIII, and d, f, h, j and l were also digested with Hinf1.

created by the secondary structure of the RNA, fragments generated by complete digestion with RNase T₁ or by controlled aniline cleavage⁹ (size range 15-30 nucleotides) were used for hybridization. All chloroplast DNAs showed one prominent signal of 7-10 kilobases (kb) in length and two bands of low intensity, whereas the nuclear DNA preparations gave no specific hybridization signal (Fig. 3). HinfI cleaved the prominently hybridizing HindIII fragments into DNA of lower relative molecular mass. Although the nuclear genomes obviously contain DNA sequences related to RNA^{DALA}, the presence of a strongly hybridizing DNA fragment in all chloroplast DNAs make it unlikely that this RNA is encoded in the nucleus.

A few examples exist for the involvement of tRNA in reactions other than protein biosynthesis, among them the synthesis of aminoacyl-phosphatidyl-glycerol²⁹, the N-terminal addition of amino acids to proteins³⁰ and the formation of pentapeptide bridges in bacterial cell walls³¹. More recently, tRNA has been reported to be an essential component of the ubiquitin- and ATP-dependent proteolytic system of mammalian cells³². The transamination of glutamyl-tRNA^{GIn} to yield glutaminyl-tRNA^{GIn} in Bacillus megatherium is an example of enzymatic conversion of an amino acid already linked to a tRNA³³. However, in contrast to the case reported here, glutamine formed in this reaction is then donated into peptide linkage during the

process of protein biosynthesis. For the normal requirements of intermediary metabolism in *Bacillus*, glutamine is formed by glutamine synthase^{33,34}.

Two of the three glutamate isoacceptors in barley chloroplasts are unable to substitute for the specific RNA required in δ -aminolevulinate synthesis, although they are efficiently charged by aminoacyl-tRNA synthetases present in the enzyme preparation². This raises the question of whether the RNA $^{\text{DA}}$ is tRNA species specialized just for δ -aminolevulinate formation and not used for protein biosynthesis in the chloroplast. Although the anticodon in RNA $^{\text{DALA}}$ is more highly modified than in other known tRNA $^{\text{Glu}}$ species, the answer to this question must await the results of in vitro protein synthesis experiments comparing all three pure tRNA $^{\text{Glu}}$ species. A case of such tRNA specialization is seen in Staphylococcus, where some tRNA species participate in cell wall biosynthesis but not in protein synthesis 31 .

The fact that chlorophyll biosynthesis is a light-induced process involving the concerted expression of a number of nuclear and chloroplast genes raises several questions concerning the regulation of gene expression. Of particular interest regarding the occurrence of three chloroplast glutamate isoacceptors is the question of whether they are encoded by a single gene, thus differing only in their base modifications, or whether they are derived from differentially regulated individual genes.

The formation of δ -aminolevulinate from glutamate is specific for plant chloroplasts and blue-green algae (for example, cyanobacteria³⁵). An outline of the enzymatic reaction scheme in plants based on our current knowledge is shown in Fig. 4. There are at least three distinct reactions performed by a complex set of enzymes and an RNA moiety. ATP-dependent ligation of glutamate to the RNA DALA by an aminoacyl bond is the reaction initiating this metabolic pathway. It remains to be determined whether this reaction is carried out by the normal chloroplast glutamyl-tRNA synthetase active in the glutamylation of all three chloroplast tRNA species (Fig. 1a) or whether a special enzyme is used. The glutamyl-RNA ligase present in the Blue Sepharose-bound fraction has recently been purified (P. Bruyant, unpublished). The subsequent reduction of the glutamate, activated by attachment to the RNA, is an interesting new type of reaction in which RNA is the 'cofactor' for a dehydrogenase. The fact that only one of the three tRNA Glu isoacceptors is recognized by the dehydrogenase raises interesting questions about the importance for proper recognition of primary structure and of the nucleoside modification pattern of the tRNAs. Depending on the position of the activated carboxyl group in glutamate, an additional enzyme, a hydrolase (indicated by the short arrow in Fig. 4) may be required to cleave glutamate-1-semialdehyde from the RNA^{DALA}. In the final step, free glutamate-1-semialdehyde is then the substrate for a specific aminotransferase. The RNADALA has been sequenced and identified by Southern hybridization analysis as a chloroplast tRNA^{Glu}. The fact that the RNA hybridized to chloroplast DNA of many different plant species and that a required RNA was also demonstrated for Chlamydomonas3 and Chlorella36 suggests that the RNA-dependent formation of δ -aminolevulinate for chlorophyll synthesis occurs in all plants.

Quantitative analysis of structure—activity relationships in engineered proteins by linear free-energy relationships

Alan R. Fersht, Robin J. Leatherbarrow & Tim N. C. Wells

Department of Chemistry, Imperial College of Science and Technology, London SW7 2AY, UK

Protein engineering is being used increasingly to study the fine details of the structure and activity of enzymes. How can small effects of mutation on activity be reliably quantified and systematized, and artefacts be recognized? A traditional means of doing this in organic chemistry is the use of linear free-energy relationships that link changes in rate constant for a reaction to changes in its equilibrium constant as the structure of the reagents is altered-Brønsted or Hammett plots1. We now find that the same type of plot may be applied to enzymatic reactions for variation of the structure of an enzyme with mutation. The activities of many mutant tyrosyl-transfer RNA synthetases fit structureactivity relationships which relate the rate constant for the formation of enzyme-bound tyrosyl adenylate (E.Tyr-AMP) to its equilibrium constant with enzyme-bound tyrosine and ATP (E.Tyr.ATP). This reaction results in an increase in binding energy between certain side chains of the enzyme and the side chain of tyrosine and the ribose ring of ATP. Plots of rate against equilibrium constant for a series of enzymes mutated in the relevant positions indicate that 71% of the binding energy change occurs on formation of the transition state for the chemical reaction and 90% occurs on formation of the E.Tyr-AMP.PP, complex. Other mutations show a different behaviour which is diagnostic of residues that specifically bind the transition state. Linear free-energy plots show trends and allow exceptions to be readily noted. That the activities of a large number of mutants conform to linear freeenergy equations is the best evidence yet that mutation of an enzyme can probe general properties and trends in the relationship between structure and activity.

Mutants of the tyrosyl-tRNA synthetase, which catalyses the formation of tyrosyl adenylate [equation (1)], have been gener-

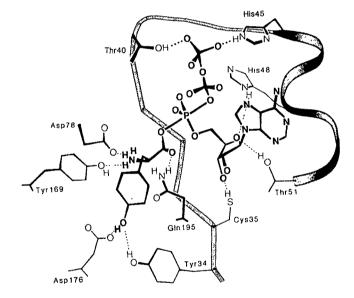

Fig. 1 Side chains of the tyrosyl-tRNA synthetase from Bacillus stearothermophilus which form hydrogen bonds with the transition state of ATP and tyrosine during the formation of tyrosyl adenylate (from ref. 5).

ated by site-directed mutagenesis and studied by kinetics²⁻⁴.

$$E+Tyr+ATP \Leftrightarrow E.Tyr-AMP+PP_i$$
 (1)

These mutants have been altered in side chains that make hydrogen bonds with the substrates (Fig. 1). Model building followed by mutagenesis has revealed that there is a major catalytic factor caused by just two side chains that contribute binding energy to the γ -phosphate of ATP only when it is in the transition state (Thr 40 and His 45)⁵. Further, the binding energies of groups far removed from the site of reaction are also used to increase the chemical rate constants for the reaction (Tyr 34, Cys 35, His 48, Thr 51 and Tyr 169)⁶. Subsequent studies have measured the complete free-energy profiles for activation of tyrosine by the mutant enzymes^{7,8}. The comparison of these

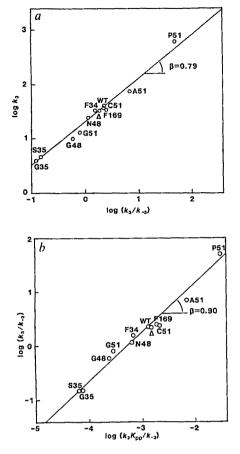

Fig. 2 a, Plot of $\log k_3$ against $\log (k_3/k_{-3})$ for equation (5) for mutation of Tyr 34, Cys 35, His 48, Thr 51 and Tyr 169. The mutations are indicated by the one-letter code apart from Δ , which represents the truncated enzyme lacking the tRNA-binding domain 10. Data are from refs 6 and 7 and T.N.C.W. (unpublished). The plot is equivalent to a plot of $G_{[E,Tyr-ATP]} - G_{E,Tyr-ATP}$ against $G_{E,Tyr-AMP,PPi} - G_{E,Tyr-ATP}$, where G is Gibbs free energy and [E,Tyr-ATP] is the transition state. b, Plot of $\log (k_3/k_{-3})$ against $\log (k_3 K_{pp}/k_{-3})$. This is equivalent to a plot of $G_{E,Tyr-AMP,PPi} - G_{E,Tyr-ATP}$ against $G_{E,Tyr-AMP} - G_{E,Tyr-ATP}$. Note that individual variations in rate and equilibrium constants are seen as deviations from the regression line.

with the profile for wild-type enzyme gives the apparent binding energy of the relevant side chain with the substrates, transition states and intermediates throughout the reaction. These data have been analysed in each individual case to show how the changes in binding energy affect the rate and equilibrium constants for the interconversion of free and enzyme-bound species. Several of the side chains that bind the side chain of tyrosine and the ribose ring of ATP appear to stabilize the enzyme-bound tyrosyl adenylate complex (E.Tyr-AMP) more than the transition state for its formation and more still than the initial enzyme-substrate ternary complex (E.Tyr.ATP)^{7,8}. By this type of analysis, we are building up a picture of how each side chain contributes to catalysis.

The question most frequently asked about this approach is: How do we know that alteration of a side chain by mutagenesis does not cause additional structural changes in the enzyme which lead to artefactual results? X-ray crystallography of mutants can provide important evidence but may miss a series of small changes or the existence of conformational changes in solution. Further, although crystallography and spectroscopy can solve the structures of the stable states of the enzyme and its substrates, they do not give direct information on the structure

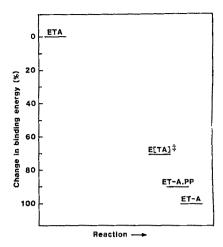

Fig. 3 Summary of the average binding-energy changes calculated for residues Tyr 34, Cys 35, His 48, Thr 51 and Tyr 169 on going from the E.Tyr.ATP complex (ETA) to the transition state (E[TA][‡]) to the first intermediate, E.Tyr-AMP.PP, (ET-A.PP), to the final intermediate, E.Tyr-AMP (ET-A).

which is important for the determination of rate, the transition state. The only way this can be probed experimentally at present is by kinetics. A possible way of both probing the structure of the transition state and detecting artefacts is the use of linear free-energy plots. In these, plots of rate constant against equilibrium constant are made for a reaction in which the structures of the reagents are systematically varied. The plots can give information on how much the transition state resembles starting materials or products. The plots assume that there is the relationship between the equilibrium constant K of a reaction and the rate constant k for the formation of products of the general form:

$$k = AK^{\beta} \tag{2}$$

where A and β are constants. The plot of $\log k$ against $\log K$ when equation (2) holds is a straight line of slope β [equation (3)].

$$\log k = \text{constant} + \beta \log K \tag{3}$$

Since $\log k$ is proportional to the free energy of activation of the reaction, ΔG^{\dagger} , and $\log K$ is proportional to the free-energy change for the equilibrium, ΔG_{e} , equation (3) is equivalent to:

$$\Delta G^{\dagger} = \text{constant} + \beta \Delta G_{\bullet} \tag{4}$$

A qualitative interpretation of equations (2) to (4) is that, all things being equal, a value of β which is close to zero means that the transition state resembles starting materials, and a value of β close to 1 means that the transition state resembles products. Linear free-energy relationships in simple organic reactions generally measure the inductive effects of groups on rate and equilibrium constants. In enzymatic reactions, however, changes in structure remote from the seat of reaction result in changes of binding energy (ref. 9 and A.R.F., unpublished). Can linear free-energy relationships be applied to the changes in rate and equilibrium constants which occur when enzyme structure is varied as in a site-directed mutagenesis experiment? If so, the values of β will, in general, measure the fractions of total changes in binding energy.

We have measured all the necessary rate and equilibrium constants defined in equation (5) to construct plots for different stages of the reaction.

$$E \stackrel{K_{i}}{\rightleftharpoons} E.Tyr \stackrel{K'_{a}}{\rightleftharpoons} E.Tyr.ATP \stackrel{k_{3}}{\rightleftharpoons} E.Tyr-AMP.PP_{i} \stackrel{K_{pp}}{\rightleftharpoons} E.Tyr-AMP$$
(5)

As Fig. 2 shows, a plot of $\log k_3$ against $\log(k_3/k_{-3})$ for mutants in the side chains which bind the side chain of tyrosine and

the ribose ring of ATP fits an excellent straight line of slope $\beta = 0.79$. This means that 79% of the binding-energy change on E.Tyr.ATP going to E.Tyr-AMP.PP_i is realized in the transition state for the reaction. Also plotted in Fig. 2 is $log(k_3/k_{-3})$ against $\log(k_3 K_{\rm pp}/k_{-3})$. This is in reality a plot of the change in binding energy on going from E.Tyr.ATP to E.Tyr-AMP.PP; against the change in going from E. Tyr. ATP to E. Tyr-AMP+PP_i. The slope of 0.9 shows that 90% of the change in binding energy on forming E.Tyr-AMP occurs at the stage of formation of E.Tyr-AMP.PP_i. Figure 3 summarizes the changes in binding energy. There is a gain in binding energy on going from the ternary complex E.Tyr.ATP to the enzyme-bound tyrosyl adenylate complex, E.Tyr-AMP; 71% of this binding energy is realized in the transition state and 90% in the other intermediate. E.Tyr-AMP.PPi.

The above type of behaviour applies when the residues concerned show a uniformly progressive change in binding energy as the reaction proceeds. A different pattern is expected when the mutation involves residues that bind the transition state of the substrates well but bind the unreacted substrates and products only poorly. Such behaviour should lead to values for β which are much greater than 1. For example, in the extreme case, where a residue binds only at the stage of the transition state, mutation of that residue will not affect the equilibrium constant of the reaction but will affect the rate; that is, β should tend to infinity. This is found quite dramatically with residues Thr 40 and His 45 (Fig. 4), which have already been implicated

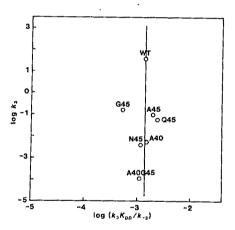

Fig. 4 Plot of $\log k_3$ against $\log (k_3 K_{pp}/k_{-3})$ for the mutation of residues Thr 40 and His 45 which are involved in transition-state binding only⁵. This is equivalent to a plot of $G_{\text{[E.Tyr-ATP]}}$ $G_{\text{E.Tyr.ATP}}$ against $G_{\text{E.Tyr.AMP}} - G_{\text{E.Tyr.ATP}}$. Data are from ref. 5 and R.J.L. (unpublished).

in such a mode of catalysis⁵. The very high value of β found indicates that they are highly specific for the transition state.

It is quite remarkable that plots in Fig. 2 are so similar to those found for linear free-energy relationships in simple organic reactions. Indeed, the fit to such plots is as good as many examples from physical organic chemistry. Why are the linear free-energy relationships followed so well considering the likelihood of disturbing the structure of the protein? The answer is probably because we have restricted our mutations to the most conservative changes, which have made only small perturbations in the structure.

The demonstration that certain structural changes of the tyrosyl-tRNA synthetase cause changes in rate which may be described satisfactorily by linear free-energy equations is important for the following reasons. First, the equations combine the data from many experiments and so bring order to them. Second, they quantify aspects of the transition state structure; in particular, they show how much the interactions in the transition state resemble those in the enzyme-substrate and the enzymeintermediate complexes. Finally, the equations show trends; any mutant that deviates from the trend is immediately apparent.

The last point is particularly important. The results of any one individual mutation can be challenged on the grounds that the mutation might cause a significant change in the protein structure. However, when a whole series of mutational experiments can be fitted to a linear free-energy equation, there is overwhelming evidence that each mutant shows part of a general phenomenon of the relationship between structure and activity. This type of analysis can be applied to any enzymatic reaction where both rate and equilibrium constants may be measured.

Directional electron transfer in ruthenium-modified horse heart cytochrome c

Rolf Bechtold, Christa Kuehn, Chris Lepre & Stephan S. Isied*

Department of Chemistry, Rutgers, State University of New Jersey, New Brunswick, New Jersey 08903, USA

Cytochrome c can be modified by [(NH₃)₅Ru^{II/III}-] specifically at the imidazole moiety of histidine 33, and we have recently discussed the thermodynamics and kinetics of electron transfer within this modified protein¹⁻⁵. X-ray crystal structures of the oxidized and reduced forms of tuna cytochrome c^6 indicate that the separation between the haem group of cytochrome c and the ruthenium label is 12-16 Å. Internal electron transfer from the [(NH3)5Ru11-] centre to the Fe(III) haem centre occurs with a rate constant $k \approx 53 \text{ s}^-$ (25 °C) ($\Delta H^{\ddagger} = 3.5 \text{ kcal mol}^{-1}$, $\Delta S^{\ddagger} = -39 \text{ EU}$), as measured by pulse radiolysis. The measured unimolecular rate constant¹, $k \simeq$ 53 s⁻¹, is on the same timescale as a number of conformational changes that occur within the cytochrome c molecule⁷⁻⁹. These results raise the question of whether electron transfer or protein conformational change is the rate limiting step in this process. We describe here an experiment that probes this intramolecular electron transfer step further. It involves reversing the direction of electron transfer by changing the redox potential of the ruthenium label. Electron transfer in the new ruthenium-cytochrome c derivative described here is from haem(II) to the Ru(III) label, whereas in $(NH_3)_5$ Ru-cytochrome c the electron transfer is from Ru(II) to haem(III). Intramolecular electron transfer from haem(II) to Ru(III) in the new ruthenium-cytochrome c described here proceeds much slower (>105 times) than the electron transfer from Ru(II) to haem(III) in the (NH₃)₅Ru-cytochrome c. We therefore conclude that electron transfer in cytochrome c is directional, with the protein envelope presumably involved in this directionality.

^{*} To whom correspondence should be addressed.

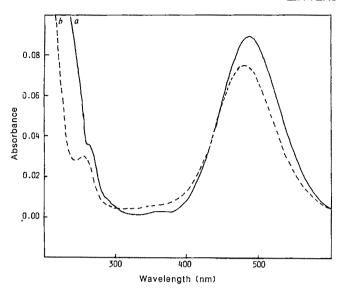

Fig. 1 a, Ultraviolet-visible spectrum of the Ruⁿ(NH₃)₄(isn)-peptide fragment containing His 33. b, Ultraviolet-visible spectrum of the model complex, trans-[Ru(NH₃)₄(isn)-N-acetylhist-aminet²⁺.

The new ruthenium-modified cytochrome c has trans-[Ru(NH₃)₄(N \bigcirc C \bigcirc)]- covalently bound to His 33

and was synthesized using techniques described earlier³. Ruthenium analysis by direct coupled plasma atomic absorption spectroscopy showed the presence of 1 mol of ruthenium per mol of iron. The ultraviolet-visible spectra of the oxidized derivative indicated no difference from that of native cytochrome c(III). Comparison between the tryptic digests of the native cytochrome c and the $[Ru(NH_3)_4(isn)-cyt\,c]$ (isn = isonicotinamide) by HPLC showed the presence of a new fragment in the ruthenium-modified product. The amino-acid composition of this fraction (Asp, 1.04; Thr, 0.97; Gly, 2.01; Leu, 1.62; His, 0.94; Pro, not detected) corresponds to amino acids 28-35 of cytochrome c. (The new cleavage site for trypsin may have resulted from the hydrophobicity of the isonicotinamide ligand in combination with the positive charge of the ruthenium centre.)

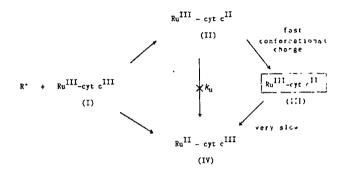

The ultraviolet-visible spectrum of this peptide fragment after reduction with ascorbic acid (Fig. 1a) closely resembles that of the model compound trans-[Ru^{II}(NH₃)₄(isn)(N-acetylhist-amine] (Fig. 1b). Figure 2a shows a differential pulse polarogram (DPP) of [Ru(NH₃)₄isn-cyt c]. Two waves are observed, one corresponding to the haem iron (II/III) of cytochrome c (0.26 V versus normal hydrogen electrode (NHE)) and the other corresponding to [Ru^{II/III}(NH₃)₄isn-] (0.44 V versus NHE). Figure 2b shows the DPP of [(Ru(NH₃)₅-cyt c] for comparison¹.

A spectrophotometric titration of the fully reduced ruthenium-modified cytochrome c, $[Ru^{II}(NH_3)_4 isn-cyt c^{II}]$, with the trans- $[Ru(NH_3)_4 (isn)_2]^{3+}$ oxidant $(E^\circ = 0.70 \text{ V};$ estimated from ref. 10), was carried out to determine the stoichiometry of the oxidation. Colour changes in the trans- $[Ru(NH_3)_4 (isn)_2]^{3+}$ species during titration enable the oxidation of the haem and the ruthenium sites to be observed sequentially. Two mol of trans- $[Ru(NH_3)_4 (isn)_2]^{3+}$ oxidant were required per mol of the cytochrome c derivative.

The kinetics of intermolecular oxidation of the haem site in $[Ru^{II}(NH_3)_4]$ isn-cyt c^{II} with $[Fe(CN)_6]^{3-}$ or $trans-[Ru(NH_3)_4-(isn)_2]^{3+}$ is similar to the oxidation of native cytochrome c(II) by inorganic oxidizing agents¹¹. This indicates similar environments of the haem site in the native and the modified protein.

As Fig. 2 shows, the two ruthenium-cytochrome c derivatives, $[Ru(NH_3)_4 isn-cyt\ c]$ and $[Ru(NH_3)_5 - cyt\ c]$, possess Ru(II/III) potentials approximately equidistant in the positive and negative directions, respectively, from the potential of Fe(II/III) haem $(\Delta E^\circ = 0.18 \text{ V} \text{ and } 0.11 \text{ V})$. Thus, on the basis of driving force¹², the rate of intramolecular electron transfer from cytochrome c(II) to $[Ru^{II}(NH_3)_4 isn-]$ should be equal to or slightly greater than the rate of intramolecular electron transfer measured from $[Ru^{II}(NH_3)_5]$ to cytochrome c(III) $(k \approx 53 \text{ s}^{-1})$.

Reduction of a solution of [Ru^{III}(NH₃)₄isn-cyt c^{III}] in 0.1 M phosphate buffer pH 7 (scheme 1) with the radicals derived from

Ru = Ru(NH₃)₄(isn)-

Scheme 1

either isopropanol or formate (R') using pulse radiolysis techniques is shown in Fig. 3.

The haem site is reduced at the expected rate¹, but no intramolecular electron transfer is observed from the Fe(11) haem to the $[Ru^{III}(NH_3)_4 isn-]$ site on the timescale of the experiment (2 s). This result is completely unexpected when compared with the $[Ru(NH_3)_5$ -cyt c] derivative. In both the $[Ru(NH_3)_4 isn-$ cyt c] and the $[Ru(NH_3)_5$ -cyt c] derivatives, the ruthenium is bound to the identical His 33 site and the difference in driving

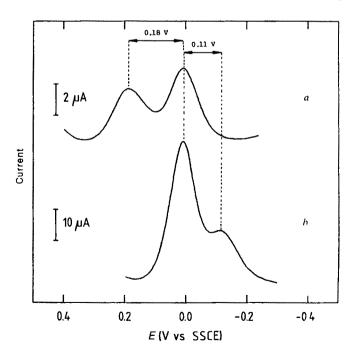

Fig. 2 Differential pulse polarograms of $[Ru(NH_3)_4(isn)-cyt\ c]$ (a) and $[Ru(NH_3)_5-cyt\ c]$ (b); volts versus standard saturated calomel electrode (SSCE); 2-mm gold disk electrode; scan rate = 2 mV s^{-1} ; pulse amplitude, 25 mV; approximately 0.25 μ mol $[Ru^{III}-cyt\ c^{III}]$ in 0.1 M NaClO₄, 0.01 M bipyridine, 0.08 M phosphate buffer, pH 7.

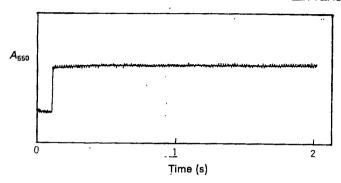

Fig. 3 Absorption change at 550 nm for the reduction of [Ru^{III}(NH₃)₄(isn)-cyt c^{III}] with isopropanol radical. The small absorbance increase at long times in the pulse radiolysis experiment is due to the reduction of the haem site in Ru(III)-cyt c(III) by secondary radicals. A similar increase in absorbance is observed at long times with the native cytochrome c(III).

force between each ruthenium complex and the haem iron is of a similar magnitude.

Scheme 1 shows the proposed sequence of events after reduction of [Ru^{III}(NH₃)₄isn-cyt c^{III}] using pulse radiolysis or chemical techniques. Following reduction, species II and IV are rapidly formed. ku is the expected rate constant for intramolecular electron transfer between species II (the kinetically stable product) and species IV (the thermodynamically stable product). However, no such reaction is observed and

Table 1 · Chemical and pulse radiolysis reduction of $[Ru^{II}(NH_3)_4isn-cyt c^{III}]$

Reductant*	% Haem reduced	%[Ru ^{III} (NH ₃) ₄ (isn)-His 33] reduced
$[Ru(NH_3)_6]^{2+}$	80 ± 10	20 ± 10
CO_2^-	40 ± 5	60±5 ·
(CH₃)₂ĊOH	60 ± 5	. 40±5

Data were obtained by monitoring the increase in absorbance at wavelength $\lambda = 550 \,\mathrm{nm}$ for the reduction of the haem site and the increase in absorbance at $\lambda = 504$ nm for the reduction of the Ru(III) site. * One mol of $[Ru(NH_3)_6]^{2+}$ was used per mol $[Ru^m(NH_3)_4$ isn-cyt c^m . CO₂ and (CH₃)₂COH were formed by pulse radiolysis from formate and 2-propanol, respectively.

instead species II undergoes a rapid (conformational) change to species III. Species III is long-lived (several hours), but can be converted to species IV by the use of a mediator, $[Ru(NH_3)_5 pyridine]^{3+}$ (redox potential, $E^\circ = 0.3$ V versus NHE, in between the reduction potentials of cytochrome c and the $[Ru^{II}(NH_3)_4 isn]$ sites). This mediator oxidizes the haem c(II), resulting in the formation of [Ru(NH₃)₅pyridine]²⁺ which in turn reduces the [Ru^{III}(NH₃)₄isn] site on cytochrome c by intermolecular reactions, as observed from spectral changes on the haem and the ruthenium sites. If species III is generated and kept without this mediator, it decays by a bimolecular pathway on a timescale of several hours ($k \approx 10 \pm 8 \text{ M}^{-1} \text{ s}^{-1}$; studied over a concentration range of 5-50 μM). The chemical reduction of $[Ru^{III}(NH_3)_4$ isn-cyt c^{III}] with 1 mol of $[Ru(NH_3)_6]^{2+}$ resulted in the formation of the kinetic intermediates II and III (scheme 1 and Table 1), as observed in the pulse radiolysis experiment.

The combined results of these ruthenium modification experiments constitute strong evidence for directional electron transfer in horse heart cytochrome c, where the intramolecular electron transfer pathway for the reduction of the haem site is more facile than that for the oxidation of the haem by the Ru(III) complex. This type of behaviour probably results from a conformational change in the protein, such that when cytochrome c(III) is reduced to cytochrome c(II), the reduced haem possesses a high kinetic barrier for intramolecular oxidation from a long distance (12-16 Å). It is noteworthy that intermolecular oxidation of cytochrome c(II) by redox reagents such as cobalt phenanthrolines and ferrocene is very rapid, presumably because there is no restriction on the approach of the oxidant to a favourable haem site for reduction, an option not available in this long-range intramolecular oxidation reaction in Ru(NH₃)₄isn-cyt c.

Earlier work on cytochrome c by Tabushi et al. 13,14 using stopped-flow circular dichroism techniques showed the presence of intermediates formed during the reduction of cytochrome c(III), but not during re-oxidation. These results led the authors to suggest that the reduction pathway is different from the oxidation pathway¹³. Furthermore, theoretical and experimental evidence showed conformational differences between the oxidized and reduced forms of cytochrome c in solution 15-18

This directionality of electron transfer in cytochrome c may have great significance in the biological function of cytochrome c, as it may mean that cytochrome c and perhaps other electron transfer proteins undergo electron transfer accompanied by conformational changes. These conformational changes can modify the barrier for electron transfer in different directions. Our observations also call for a differentiation between the formalisms used to describe electron transfer in small molecules and those needed for electron transfer proteins. For example, the meaning of the term 'self exchange' for an electron transfer protein should be redefined, since a multi-step process is involved in the electron exchange of these proteins.

Diversity of haematopoietic stem cell growth from a uniform population of cells

THE stochastic model for haematopoietic stem cell differentiation 1 with the addition of a maturation pathway and a 'resting' G_0 phase provides unifying explanations for three characteristics of the growth of colonies developing in the spleens of irradiated mice that have been injected with haematopoietic cells (Fig. 1).

First, it predicts that a homogeneous cell population can produce a high proportion of visible colonies that disappear between the 7th and 12th day of colony growth, with a nearly equal number of cells appearing during this interval; however, this requires the proviso that the self-renewal probability of colonyforming cells does not increase from the normal steady-state value until a few days after the irradiation and injection of haematopoietic cells. Second, the tiny transient erythroid colonies (devoid of colony-forming cells) observed in erythropoietically stimulated irradiated mice² can be predicted if there is a reduction in the threshold size for visibility, due to the increased contrast of more mature erythroid cells. Thus, these colonies may be produced by the same homogeneous population of multipotential cells producing the late-disappearing and lateappearing colonies, but such colonies are those which run out of stem cells early, 60% predicted theoretically³, and so are not usually seen. Third, the late appearance of colonies (with higher colonyforming content) observed after injection of bone marrow cells from donor mice that have been treated with the anticancer agent 5-fluorouracil⁴ can be predicted by a 15% reduction in the number of maturing cell generations.

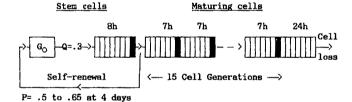

Physical cell separation shows unambiguously that spleen colony-forming cells are heterogeneous, but does not argue forcibly for the existence of a separate subpopulation of committed spleen colony-forming cells comparable in number to the multipotential population. We therefore suggest that the experimental results of Magli et al.5 fail to provide satisfactory evidence for the widely accepted claim "that the spleen colony method measures pluripotential stem cells only where macroscopic colonies are scored 11 days or later". Moreover, up to 80% of 10-day colonies contain colony-forming cells⁶. Thus, there is no compelling reason for scoring colonies later than 10 days, with the attendant increase in such technical problems as fewer countable colonies, linearity of colony counts with number of cells injected due to their larger size, possible migration from other sites, appearance of endogenous colonies and more frequent difficulty with animal survival. Moreover, these date do not necessarily require a reassessment of work carried out over the past 20 years using this important assay for haematopoietic stem cells.

This highly oversimplistic model with quite uncontroversial assump lions, demonstrates that results previously explained by postulating separate stem cell populations or selective drug sensitivity can be explained elegantly by a homogeneous population responding in different ways. Unless the minimum number of assumptions required . explain particular experimental data is found, it is unlikely that we will acquire a better understanding of the nature and regulation of haematopoietic stem cells. Our unifying model reverses the tendency to postulate a new cell population each time a new type of experimental result is observed. Elsewhere it is shown that these conclusions support the specific mechanism for the regulation of the number of haematopoietic stem cells proposed previously⁷, that they provide a straightforward explanation for the 'puzzle' concerning stem cell regeneration from cells with impaired self-renewal capacity⁸ and that the equation³ for calculating sel!-renewal has been misapplied.

ISCOVE ET AL. REPLY—Blackett, Necas and Frindel show that our observations of transient and late-appearing splcen colonies can be simulated by assuming an initially homogeneous colony-forming cell population and making an ad hoc adjustment of self-renewal probability. They conclude that our data do not prove that only the later colonies arise from pluripotential cells capable of extensive proliferation, and therefore claim that "there is no compelling reason for scoring colonies later than 10 days ...".

The essential point of our report was that early colonies are transient, and that the later-appearing multilineage colonies which contain primitive precursors are not derived from the early colonies. Therefore, the character of later colonies could no longer be invoked as proof of the primitiveness of the cells originating the early colonies. Faced with transient early colonies that had no primitive cells and contained practically only terminally differentiating erythroid cells, and now lacking any evidence for derivation from pluripotential precursors, we proposed the straightforward interpretation: that early and late colonies arise from different kinds of cell, and that the early transient colonies might in fact arise from committed precursors possessing limited proliferative potential.

There is an important additional consequence of the unrelatedness of early and late colonies which concerns the question of probability of 'self renewal'. The concept that this probability could increase during the development of spleen colonies was originally invoked to explain their increasing relative content of primitive precursors with time. An increase in self renewal probability during the course of spleen colony growth is the central assumption in the simulation performed by Blackett et al. However, our result removed both the need for this postulate and the evidence supporting it.

The important issue now is whether both early and late spleen colonies arise from an initially homogeneous precursor cell population. There is now abundant evidence that they do not: (1) Eight-day spleen colony-forming units (CFU-S[8]) are killed by 5-fluorouracil, while CFU-S[12] are relatively spared². (2) In sublethally irradiated mice, CFU-S[7] initiate DNA synthesis whereas CFU-S[11] do not³. (3) CFU-S[7] are twice as sensitive as CFU-S[11] to photoinactivation by the membrane-binding agent merocyanine 540 (ref. 4). (4) CFU-S[7] are resistant to inactivation by anti-Qa-m2 antibody plus complement, while most CFU-S[12] are inactivated⁵. (5) CFU-S sorted on the basis of binding of pokeweed mitogen segregate into a population high in proliferative capacity and ability to generate primitive precursors, and a second population having lower proliferative capacity and relatively enriched in CFU-S[7] (ref. 6). Sorting on the basis of H33342 staining⁷ and anti-H-2K binding similarly segregates cells forming early and late spleen colonies.

These experiments show conclusively that early and late spleen colonies are derived from different and separable types of precursor cells, and directly refute the model proposed by Blackett et al. Until contrary evidence appears, the available negative evidence provides more than adequate reason to question the notion

that spleen colonies scored at early times arise from pluripotential precursors with extensive proliferative potential.

DNA fingerprint analysis in immigration test-cases

RECENTLY, Jeffreys et al.1 used 'fingerprints' of mini-satellites to check maternity in an immigration case. I do not dispute their conclusion that the boy (X) seeking immigration was the son of the putative mother (M), and not the son of an unrelated woman or of a sister of M, but their statistical analysis includes some deficiencies.

A complete analysis of the pedigree, which involved X, M and three undisputed offspring (B, S1 and S2) of M, requires construction of a series of likelihoods taking account of the distribution of DNA bands in each individual, for example information about homozygosity of particular mini-satellites is provided by whether or not all the sibs shared any particular band. It is useful first, however, to reanalyse the summary data given by Jeffreys et al.1 in which, having assumed that X had the same father as B, S1 and S2, they deduced that 25 fragments, all of which were present in M, must have been inherited from X's mother. Following Jeffreys et al., I assume that shared bands represent identical alleles at a hypervariable locus, and that the frequency (x) is the same for all bands. For the model where M is the aunt of X, I have computed the probability that M has the band and X has inherited his from a sister of M (Table 1). The relevant likelihood ratio is $L_{\rm a}/L_{\rm m} = 0.63^{25} \doteq 10^{-5}$. Jeffreys et al. computed, instead, the probability that M and a sister (assumed, but not stated, not to be an identical twin) share a band, which is not relevant because the band has to be

transmitted to X. Their value of 0.62 is so close to 0.63, however, that overall probabilities are little different.

The basic data on the 95 bands observed and the computation of likelihood in terms of the p_{ijk} , the prior probabilities of occurrence of the bands in different family members, are given in Table 2. Computation of pijk for each model is straightforward, but tedious.

For models unrelated (u) and mother (m) all possible genotypes of mother and father have to be considered. For example, if both are heterozygotes for a band, the prior frequency of the mating is $4q^2(1$ $q)^2$, i=1 since M has the band, and the conditional probabilities that k=0, 1, 2and 3 are 1/64, 9/64, 27/64 and 27/64, respectively; the conditional probability that j = 0 is 1/2 - q/2 under model u and 1/4 under model m. Summation over combinations of genotypes gives the p_{ijk} .

For model a, where M is the aunt, a two-stage process can be used. First, all possible matings among the parents of M and her sister and for these the conditional probabilities of each genotype of M and of the band inherited by X from his mother (that is, M's sister) have to be enumerated. For example, if both the grandparents are heterozygotes, the joint probability that M is a heterozygote and X does not inherit the band from his mother is 1/4. From these data, prior probabilities of each of the possible inheritance patterns can be computed as a function of q. Second, these alternatives have to be taken with each possible genotype of the father, and the conditional probabilities that X has the band and the number of sibs with the band computed. For example, if r_3 denotes the prior probability that M is a heterozygote and X does not inherit the band from his mother, the prior probability of the corresponding mating of M to a heterozygote is $2q(1-q)r_3$, i=1 (M is a heterozygote), j=0 with probability 1/2, and k=0 with probability 1/64. Subsequent summation yields the p_{iik} .

The likelihoods can be obtained for any value of q, but as there is no prior knowledge of band frequency in the Ghanaian population, q has to be estimated for each model by maximizing the likelihood. The important likelihood ratio is $L_a/L_m =$ 0.000035 (Table 3) which, though six times higher than the probability ratio calculated by Jeffreys et al., is still very small. If the likelihood computations are repeated with q = 0.14, the value previously used¹, the corresponding ratio is much reduced (1.3×10^{-7}) ; and 0.14 was at the upper end of frequencies observed in British caucasians². Also, because frequencies of bands differ2, these likelihood calculations overestimate L_a/L_m if M is indeed the mother.

There are many assumptions in these analyses, but there seems no justification in avoiding a formal method whatever the

Table 1 Probability that M carries the band and X has a maternally derived band for each model in the reduced analysis

Model	Probability	Likelihood ratio
M unrelated to X (u)	qx	$L_{\rm u}/L_{\rm m} = 0.26^{25} = 2.4 \times 10^{-15}$
M aunt of X (a)	q(1+x)/2	$L_{\rm u}/L_{\rm a}=0.413^{25}=2.5\times10^{-10}$
M mother of X (m)	\boldsymbol{q}	$L_{\rm a}/L_{\rm m} = 0.63^{25} = 9.6 \times 10^{-6}$

x, Band frequency, assumed to be the same for each band (x = 0.26); q, allele frequency $(x=2q-q^2).$

Table 2 The number of bands (n_{ijk}) present in the sample with i = (0)1 if the band is (absent) present in M, j = (0)1 if the band is (absent) present in X, k = 0, 1, 2, 3 is the number of sibs with the band, and computation of likelihood

	Band absent in $X(j=0)$			Band present in $X(j=1)$			(j = 1)		
No. of sibs	0	1	2	3	0	1	2	3	
Band absent in M $(i=0)$	-	10	4	0	0	7	9	2	
Band present in M $(i=1)$	2	5	8	4	3	13	13	15	

 p_{ijk} Probability corresponding to n_{ijk} . The log likelihood is computed conditional on the occurrence of the band in at least one individual, with summation excluding the 000 class: $\ln L = \sum_{i} \sum_{k} \sum_{k} n_{ijk} [\ln p_{ijk} - \ln p_{000}].$

Table 3 Maximum likelihood estimates of allele frequency (q_{max}) for each model, together with corresponding log likelihoods (ln L) and likelihood ratios in the full analysis, assuming B, S1, S2 and X all have the same father

Model	q_{max}	$\ln L$	Likelihood ratios
u	0.32	-256.78	$L_{\rm u}/L_{\rm m} = 2.1 \times 10^{-9}$
a	0.26	-247.05	$L_{\rm u}/L_{\rm a} = 5.9 \times 10^{-5}$
m	0.18	-236.78	$L_{\rm a}/L_{\rm m} = 3.5 \times 10^{-5}$

model. As more information about the frequencies and inheritance of the minisatellites becomes available, the models can be refined and the obvious power of the DNA-fingerprint technique utilized. Nevertheless, I do not believe that comparisons such as these give positive identification as suggested¹, only evidence that alternatives are highly unlikely.

I thank John Brookfield for providing the basic data, Susan Brotherstone for computational assistance, and members of Leicester University's Genetics Department for financial assistance.

WILLIAM G. HILL

Institute of Animal Genetics University of Edinburgh, West Mains Road Edinburgh EH9 3JN, UK

JEFFREYS ET AL. REPLY—We thank Professor Hill for his rigorous statistical analysis of the DNA fingerprint data of this immigration test-case. We are pleased that the new analysis gives ranges of values

for the likelihood ratios which are broadly similar to ours. We reiterate that even the new analysis includes a number of assumptions. The maximum likelihood values of q are based on only one family, and will be inaccurate. It is assumed that there is no variation in q between bands. and it is assumed that bands with the same mobility are always allelic and that bands with different mobilities never are.

We admit that we have not provided positive identification of the mother of X in a mathematical sense, since no probability calculation could do this. However, we believe that the probability of error in this case is so low that it would be legally appropriate to treat the test as providing positive identification.

X; autosome translocations in females with Duchenne or Becker muscular dystrophy

RAY et al.1 recently documented their efforts at isolating the gene for Duchenne muscular dystrophy by studying DNA cloned from the breakpoint of an X;21 translocation associated with Duchenne muscular dystrophy. However, the female patient² from whom this X-chromosomal material was derived³, clearly had Becker muscular dystrophy and not Duchenne dystrophy, as she was 20 years old and still ambulant. It thus seemed timely to critically review all the reported cases of muscular dystrophy in females associated with an X; autosome translocation (Table 1) in order to try and designate them as Duchenne or Becker type.

Duchenne muscular dystrophy is an Xlinked condition with onset in early childhood and a rapidly progressive course, so that the vast majority of affected boys lose the ability to walk by the age of 12 years⁴; Becker muscular dystrophy has an identical pattern of muscle involvement but follows a more benign course, and affected males will remain ambulant beyond 16 years of age and usually into adult life⁵. Inevitably there will also be occasional cases who may fall in the grey zone between the two and be a little milder than the usual Duchenne but not quite as mild as the usual Becker type and lose ability to walk between 13 and 16 years.

Careful attention has been paid to the diagnosis of male cases of either Duchenne or Becker dystrophy in the application of restriction fragment length polymorphism (RFLP) studies and detection of deletions. It would seem logical to pay the same attention to the initial diagnosis in the X:autosome translocation females from which the DNA sequences are cloned, rather than loosely referring to them all as Duchenne muscular dystrophy, as seems to have been the current practice.

Of the twelve cases documented to date, four⁶⁻⁹ conform closely to Duchenne dystrophy and a further four¹⁰ 13 also seem to have a Duchenne severity but are still too young to be certain. One additional case¹⁴ is probably a Duchenne but was only published in abstract form with no mention of the age, which had to be surmised from the date of birth and timing of the abstract (approximately 14 years); she was said to be "unable to walk without assistance", which is also difficult to interpret. One case² conforms to Becker type and another¹⁵ also seems likely to be, but is too young (13 years) to be certain about ambulation beyond 16 years. The remaining case16 (published only in abstract form) has insufficient clinical data to draw any conclusions. Two of these cases are somewhat atypical, one10 having an associated dysmorphic syndrome and the other9 an associated Turner's syndrome.

Recent studies¹⁷⁻²⁰ have shown that the gene locus for Becker muscular dystrophy is very close to that for Duchenne and it seems likely that the two conditions are allelic. Studies with some of the probes (for example pERT 87.8)21 have shown deletions in approximately 9% (5'57) of cases of Duchenne muscular dystrophy but none with cases of Becker muscular dystrophy.

In the report of Ray et al.1, only one Duchenne dystrophy patient out of 50 studied showed a deletion for their XJ-1 clone, and this was also the only case which showed a deletion for pERT 87. In

addition, all five patients of Monaco et al.21 with deletions for pERT 87 were found to have deletions for XJ-1.

Although all the reported cases of X; autosome translocation with muscular dystrophy have apparently had the breakpoint in the same region of the short arm of the X chromosome (Xp21), there may be variations from case to case in the exact location of the breakpoint²². It may thus be of interest and importance when cloning sequences from these X-chromosome breakpoint regions, and applying them in the detection of RFLPs close to the Duchenne/Becker dystrophy genes, and looking for deletions in individual male cases, to know whether the original source came from a Duchenne or a Becker type case, and in addition to have adequate documentation of the dystrophic nature of the underlying muscle disorder.

Note added in proof: A further case, conforming to Duchenne severity, with an X:5 translocation, has recently been documented by Nevin et al.23.

WORTON REPLIES—Dubowitz raises a very valid concern about the phenotypes of girls with myopathic disease secondary to an X; autosome translocation. Certainly the X;21 translocation patient whose junction has been cloned has a mild form of muscular dystrophy more like the Becker form of the disease and should perhaps be reclassified as such.

However, there are two very important points to be made about the translocation patients in general. First, all have translocation exchange points in band Xp21 despite the fact that some have a severe (Duchenne) phenotype and others appear to have the milder (Becker) phenotype. This fits with the linkage data that map the gene for both Becker and Duchenne muscular dystrophy to this region of the X chromosome. As Dubowitz points out the two diseases may in fact be due to allelic mutations at the same locus. Thus, although it is important to have the phenotype of patients accurately described, the Duchenne and Becker variants of muscular dystrophy may simply represent different manifestations of the same disease.

The second important point, and one not discussed by Dubowitz, is that the expression of muscle disease in these girls who are heterozygous for the mutation (translocation) is a function of the nonrandom inactivation of the normal X chromosome carrying the wild-type allele. In many of the girls examined, the preference for normal X inactivation is not complete; up to 10% of the lymphocytes examined displayed a late replicating (inactive) translocation X and an early replicating (active) normal X. If this pattern holds in muscle, a proportion of the nuclei in a multi-nucleated myotube may be capable of producing the normal gene product. Since the 50% level of gene product expected of a non-translocation carrier female is sufficient to prevent the disease, a level of 5% or 10% may well be sufficient to modify the severity of the disease. In translocation patients a mutation at the 'Duchenne gene', therefore, may result in a Becker phenotype. This complicates the picture and suggests that neither term is really appropriate to the translocation females. Only through detailed genetic studies of the Becker/Duchenne muscular dystrophy locus will the true relationship between the two diseases be understood.

Matters Arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in Nature. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 500 words and the briefest of replies, to the effect that a point is taken, should be considered.

TERRESTRIAL ORIGIN OF THE MOON

A better way to get uniform band sp Wedge-shap

No longer need you resort to multiple loading with its increased time and greater required sample volumes. Whether for nucleotide separations in agarose gels or sequencing in acrylamide gels, the technique of wedge-shaped field strength gradients lets you get linearly spaced bands for maximum resolution and ease of reading. Two new instrument systems from LKB render the technique rapid, reliable

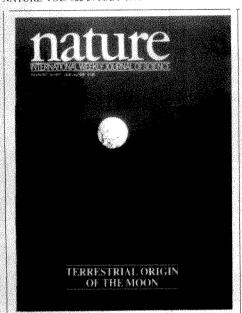

and above all, reproducible.

In the Maxiphor" horizontal electrophoresis unit (A), it is the simplest thing in the world to pour wedge-shaped agarose bridge gels directly on the central platform when adjustable legs beneath the cathode dam are extended. Gels can be run rapidly at high power even without external buffer circulation, the half-litre reservoir providing enough internal cooling capacity even at 500 volts. Want to use the Maxiphor for constant thickness bridge or submarine gels? Just as easily done. And you can run up to 40 samples every time.

For greatest economy and speed in fragment separations, the sibling Miniphor™ unit (B) with its integral cooling jacket lets you run submarine gels at very high power. Companion to both units is the LKB constant power supply (C) that permits regulation to 1 volt or 1 milliamp with 1 minute precision for automated runs. And completing the system is the MacroVue" transilluminator (D) whose optical design permits you to detect as little as 1 ng DNA in a single band. This instrument makes publication grade photography easy.

TGF-BETA

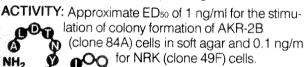

TRANSFORMING GROWTH FACTOR TYPE BETA

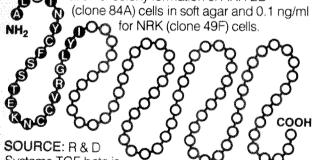

TGF-beta is an extremely stable. multi-functional growth factor, active in picomolar quantities. The effect of the molecule is largely governed by the cell line under investigation.

Some of the more notable reported effects are:1

- Reversibly confers the transformed phenotype
- Provides synergistism with EGF and/or TGF-alpha
- Inhibits growth of certain carcinoma cell lines
- Inhibits terminal differentiation of pre-adipocytes
- Promotes in vivo wound healing
- · Mimics the effects of ras oncogene transfection
- Induces c-sis expression

PURITY: greater than 96 percent homogeneous by silver-stained gels, amino acid analysis and N-terminus sequencing

Systems TGF-beta is prepared from fresh porcine platelets. Based on its molecular weight, amino acid analysis and N-terminus sequencing (22 a.a.), it is indistinguishable from TGF beta prepared from human sources.

GUIDE TO AUTHORS

Authors should be aware of the diversity of Nature's readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership.

Most are commissioned, but unsolicited reviews are welcome
(in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an italic heading of about 50 words.

Letters to Nature are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in Nature. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington). Manuscripts should be typed (double specing) on one side of the paper only. Four copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on seperate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts, in the text and should be abbreviated according to the World List of Scientific Periodicals, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be cited. Reference to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

WINORPC UNPARALLED SELECTIVITY

NATURE VOL. 322 24 JULY 1986

Half-way report on Chernobyl

The Soviet Union has published this week only the least interesting parts of its report on the Chernobyl disaster. More needs to be said.

Human error is always a convenient explanation for catastrophe. It has the advantage, for the managers of great enterprises, that a few heads can be made to roll with some publicity without interfering too directly with the underlying programme. This is the spirit in which the surviving managers of the Soviet Union's still ambitious nuclear programme will no doubt be relieved by the publication earlier this week of an abridged version of the report on the Chernobyl disaster drawn up by the official investigating committee (see page 295). None of this implies that the explanation is incorrect. There is no reason to disbelieve the Soviet statement that the managers of the plant at Chernobyl behaved foolishly and "irresponsibly", or that they deserve to lose their jobs. Indeed, most Soviet statements about Chernobyl have been shown to have been accurate.

Nevertheless, the public interest in the Chernobyl disaster stems from the general concern that the world at large should have such a good understanding of how the accident happened that it is possible to make rational decisions about the future use of nuclear power as a source of electricity. Some, no doubt, seek further information so as to berate the hapless managers of nuclear industries elsewhere. Others seek the same information in the hope that it will demonstrate that nuclear power stations can be safely operated. The curiosity of both groups is legitimate, and must be satisfied. So must be that of the people most directly affected, the population of the region stretching for 400 square kilometres around the plant. The need now is for such a full disclosure of the circumstances leading to the accident that people will be able to judge for themselves whether the Chernobyl managers were as feckless as they are now said to be.

On present evidence, there is a long way to go before the circumstances are plain. It is said that those responsible at Chernobyl had been engaged in "experiments" not authorized by the licensing authorities when the accident happened, but there is no way of telling whether this was idle technological curiosity (unlikely on the eve of the May holiday) or, instead, a desperate attempt by unorthodox means to bring a wayward reactor under control. Similarly, there is not yet a sufficient explanation of the course of the accident itself. Monitoring stations elsewhere now clearly suggest that there was a second release of radioactive material from the reactor on the second day, presumably as a consequence of a further increase of the internal temperature. but the explanation remains for the time being hidden. Yet until this information is available, people outside the Soviet Union will remain on tenterhooks. There is again no reason to fear that the Soviet Union will not keep its promise to tell all. But this once secretive government now experimenting with openness clearly still has a lot to learn.

The Soviet managers of the nuclear industry need also to learn a little more caution about reactors of the type that went wrong at Chernobyl. One of the defects of this type of reactor is that the system becomes more reactive when water is lost from the cooling system, either because it leaks away or because it turns into steam. The consequence is an uncomfortable degree of instability which can also be a source of danger when something else goes wrong. But Soviet reactors of this type also lack the large pressure-tight containment vessels that would be required

of them in the United States and most other places. It must now be a matter of grave concern whether the other reactors of this type, of which are more than twenty still in operation in the Soviet Union, can be safely allowed to continue.

In one respect, the Soviet government has responded constructively to the delivery of the report by setting up a new ministry with responsibility for the design and construction of new reactors. Obviously the intention is that the Soviet nuclear industry should in future be run on lines more appropriate for a military organization (which, in the circumstances, may be the best solution, although one conflicting with Mr Gorbachev's belief that there are too many ministries as there are). But the Soviet authorities should also pay some attention to the possible lity that there may be other, better, solutions. Notoriously, Soviet industry is perennially crippled by the bureaucratic environment in which it must function. Part (but only part) of the trouble is that managers are responsible both to the government agency or ministry which has built their plant and to the Communist Party, working through its local and regional committees. This is a recipe for the division and even dilution of responsibility. At Chernobyl, it seems to have a been a recipe for disaster as well. Nobody would expect that a single nuclear accident would persuade the Soviet Union to forsake the path Lenin mapped out, but there is good reason why the Soviet Union should now be asking whether its present arrangements for the management of industry are the only means by which the dictatorship of the proletariat can be exercised.

The plight of those exposed to fallout near Chernobyl but not acutely injured remains to be determined. Strictly speaking, it is a matter for the Soviet government, in its dealings with its own people, to decide. This week's statement says that those affected by the enormous disruption caused by the accident will be compensated, though it is not clear what that means. But there is a great need that there should be close medical surveillance of those affected for several decades to come. It is not merely that there is a great deal to learn about the effects of low-level radiation exposure, or that there are ethical considerations which require that those now at greater risk from cancer than most others should be given as timely a warning as possible, but that this is a chance for the Soviet Union to make good its previously poor record for compassion.

Packing for the summit?

There may be a Soviet-US summit this year if only a package of agreements can be found.

OPTIMISM earlier this year that 1986 would be the year in which the first arms control agreement this decade would be signed seems to be strengthening again, against the odds, and in spite of the succession of disagreements between the two major powers that have studded the past few months. And while the latest developments amount to nothing more substantial than straws in the wind, they do suggest that the two sides will eventually talk to each other, at a summit meeting later in the year. That is something for which many people will be grateful. But the likely

content of any agreement that may emerge is still a matter for conjecture. What is going on?

The straws in the wind are several. The Soviet Foreign Minister in London last week referred to the summit meeting as if it had already been arranged, apparently anticipating events. At the Stockholm meeting within the framework of the Helsinki agreements on European security, the Soviet Union has dropped its previous demands that air movements should be notified as part of the package of "confidence-building measures" on which the negotiators have been working since the beginning of 1985; now there is a chance of something to be signed at Vienna in November. Less formally, the Pugwash organization seems to have had a constructive meeting in Moscow earlier in the month. leaving many of the participants with the impression that the Soviet side is both eager for a test ban and willing to be flexible about the terms in which it might be drawn. Then President Reagan has made an encouraging speech, saying that there is much that might be done with the most recent set of proposals to the bilateral negotiations at Geneva, suggesting that an agreement may in due course emerge. Why all this sweetness and light?

The simple explanation is that both the Soviet and the US leaders wish there to be a summit, but that the Soviet side is determined that it will not allow itself this time to return emptyhanded, as in many ways it did from last year's meeting at Geneva. And the practical question is whether there is a deal of some kind that would satisfy Mr Gorbachev without sticking in Mr Reagan's throat (or the throats of his colleagues in the US administration). In many ways, guessing what the package will contain is like a children's nursery game, except that it seems clear that there can be no substantial agreement on the main issues at Geneva — reductions of strategic weapons, regulation of intermediate-range missiles and the Strategic Defense Initiative (SDI). So what else? Agreement to ratify unratified treaties, such as the threshold test-ban treaty whose provisions require the exchange of seismic data relevant to the monitoring of tests, would be a sensible step forward — one that should have been taken several years ago. But the Soviet Union, with its unilateral moratorium on testing still in force after nine months. seems anxious to secure substantial improvement in this field. That is apparently why so much attention is being paid to the several variations on the test-ban theme suggested at an informal meeting in Washington earlier in the year — comprehensive test bans whose start is delayed, or which may be interrupted occasionally. It should not hurt either side to put together a package of proposals along these lines. The obvious snag is that such a package would, by definition, not touch the centre of the problem of arms control, the regulation of major strategic weapons already deployed.

That is why the two participants in the summit should be most of all concerned to reach a new understanding on the principles by which future arms negotiations will be conducted. Too much has changed in the past few years for most people's comfort. President Reagan, who came to office nearly six years ago with a long string of cogent complaints against the then existing agreements (SALT II in particular), but who found himself forced by events and pressure from his electorate to take arms control more seriously, has now further muddied the waters by suggesting that SDI seriously offers a way round the present strategic doctrines based on mutual deterrence by the threat of a catastrophic nuclear exchange. But the plain truth is that SDI will never be as effective as its enthusiasts claim, and will probably yield nothing more than a space-borne early warning system whose existence will not substantially change the present strategic balance (if that is what it is). So the summit will be a wasted opportunity if it does not yield an understanding of the ways in which SDI has changed (or, rather, left unchanged) the rules of arms control. For pride's sake, President Reagan would need such an understanding to be limited in time, but that should be no problem.

Research directions

The British government plans to evaluate its research. But there are pitfalls.

Not much has yet been heard from Mr Kenneth Baker, the successor in the British government to Sir Keith Joseph at the Department of Education and Science, about his plans for the administration of research. Perhaps inevitably, most of his time seems to have been spent on the urgent problems of how to restore contentment and achievement to the schools, whose bruising dispute with the government over pay, working conditions and career prospects has left deep scars. Yet Mr Baker cannot overlook the problems thrown up in the past few years by the government's insistence that the costs of reorganizing (or cutting) the research councils should be met from within a static budget. Already, the political calendar has reached the point at which final estimates for the next financial year are being drawn up. Moreover, unless Mr Baker is careful (and quick), he may find that this important part of his parish has been taken away from him.

That is one implication of the decision, announced at the end of last month, that there will be a unit within the Cabinet Office for the assessment of science, technology and the relationship between them. The plan is that there should be a small group of people, run by a senior (but not too senior) civil servant, with the task of throwing light on the relationship between research spending and such benefits as may ensue. The hope is that the government will then be better placed to decide which expenditures on research will yield the greater benefits. Although the unit will be chiefly concerned with what government departments at present spend on research on their own account, and may thus be a means by which some external appraisal of the civil value of defence research is at last attained, it is inevitable that the boundaries will be fuzzy, and that the new unit's opinions will overlap with those of other organizations, the Advisory Board for the Research Councils in particular. Given its place within the bureaucracy, the new unit could powerfully influence the pattern of all publicly sponsored research.

So will the unit come to sensible conclusions? Even the passage of time may not be enough to tell, for the new unit (which still lacks a head) will almost certainly operate behind closed doors. And because its existence springs from the British government's well-known impatience with the notion that there is no way of telling in advance what investments in research are likely to be profitable, there can be no assurance that the unit will recognize as impediments to its work the two serious objections to over-closely directed research: the circumstance that successful innovation requires that companies should be both technically well-equipped and well-placed in the market and the temptation (from which civil servants are not immune) to be swept up by fashion. Mr Baker's own first claim on public attention, his advocacy of information technology as a means not merely of making Britain prosperous but of curing unemployment at the same time, was plainly timely in the early years of this government, but has not produced the expected benefits for the simple reason that Britain lacks sufficient technical skill to make full use of the opportunities that abound in information technology. It is especially shocking that the University Grants Committee, in its recent set of circulars to British universities, should have had to explain that the annual intake of students to engineering schools cannot be increased more quickly for lack of suitable school-leavers.

That is but one illustration of the truth that there is more to the problem of winning benefit from research than the backing of good ideas with sufficient funds. The most obvious pitfall for the new Cabinet Office unit is that it will be blind to pitfalls such as these. The danger is especially great because the unit's work will not necessarily be public. Even at this late stage, there may be a case for changing that.

Soviet inquiry

Chernobyl accident is blamed on human error

THE Chernobyl disaster was due to human factors or, in the words of the official dispatch, "a whole series of crude violations of the regulations for the operation of reactor installations". Such was the decision of a special session of the Politburo last weekend, after considering the report of the governmental commission that has been working at Chernobyl since the accident on 26 April. The full text of the report is expected to be published in mid-August.

According to the Politburo statement, during the night of 25/26 April, unauthorized investigations into the operating conditions of the turbogenerators were carried out on the Number 4 set, while it was out of service for a planned overhaul. Just what form these "experiments" took is unclear. The dispatch merely stated that the management and specialists of the power station had neither prepared themselves for the experiments nor coordinated them with the appropriate authorities, although they were legally bound to do so. Furthermore, there was no proper supervision of the experiments, nor were proper safety measures enforced while they were in progress. Several high officials have been dismissed for allowing this situation of "irresponsibility, negligence and lack of discipline" to develop.

By putting the blame squarely on the Chernobyl crew, the report would seem to exonerate the Soviet nuclear power programme and, in particular, the design of the RBMK reactor. But the unauthorized, unsupervised "experiments" could possibly have a more ominous explanation. In mid-May, some three weeks after the accident, there were some veiled references in the Soviet media to "experiments" at Chernobyl, followed by unattributed and unofficial reports that a malfunction on the Number 4 reactor had developed on the afternoon of 25 April, and that an emergency crew was still struggling to close it down when the explosion occurred. In this case, the "experiments" would refer to unauthorized or incorrect shutdown procedures, possibly undertaken as a last resort. In all events, the Politburo statement still fails to explain how an experiment with the turbogenerator could cause an explosion in the reactor.

Although the report was, presumably, completed only shortly before the Politburo meeting, the Soviet Procurator's Office has already instituted criminal proceedings against "the persons guilty of the accident at Chernobyl". In view of Mr Gorbachev's current drive for "open-

ness", the trial is likely to be accorded maximum publicity. The Politburo statement outlines the charges against the accused: 28 people dead, damage to the health of a large number of people, including 203 cases of radiation sickness so far, the cost of large-scale prophylactic work (including medical checks on several hundred thousand people), 1,000 km² of agricultural land taken out of production, the closure of various enterprises, the cost of evacuation and the rehousing of the evacuees, the loss of power production. The direct losses due to the accident are estimated at 2,000 thousand million roubles.

For the moment, the Politburo seems more concerned to ensure that such negligence will not occur again. Four senior officials have been dismissed: Evgenii Kulov, chairman of the state committee for safety in the nuclear power industry, G.A. Shasharin, a deputy minister of power and electrification, Aleksandr Meshkov, a first deputy minister of medium engineering, and Ivan Emelyanov, a deputy director of a research and development institute. In addition, all have been subjected to "rigorous Party penalties", as has also Bryukhanov, the former director of the Chernobyl power station who was dismissed in May

The Minister for Power and Electrification, Anatolii Mayorets, was allowed to retain his post, but suffered a Party reprimand, and the public humiliation of being told that the Politburo had taken into account that he had only recently been appointed to the job, and that, "if he did not draw the appropriate conclusions", he would suffer a more severe penalty.

A new All-Union Ministry of Nuclear Energy has been established, in order to "raise the level of management and responsibility" in the nuclear power industry, and plans are under way for the retraining and requalification of nuclear power personnel. The use of simulators in training programmes is to be expanded, presumably to familiarize personnel with emergency procedures.

Furthermore, although the RBMK reactor design appears to have been officially exonerated, the Politburo has issued an urgent "demand" to all ministries and departments that they should draw up and implement additional measures to ensure the safety of existing reactors — and an appeal to scientists of the world to cooperate in developing a new generation of fission and, in the longer term, fusion reactors.

US and Pakistan

Agreement on technology

Washington

THE United States and Pakistan have signed an agreement to establish a framework for trade in high technology goods. The agreement will make it easier for Pakistan to obtain mainframe computers and modern telecommunications equipment but will also provide specific assurance that Pakistan will neither divert the goods to other countries, nor use them in ways not approved by the United States.

Pakistan Foreign Minister Yaqub Khan and US Secretary of State George Shultz signed the agreement at the White House last week during the visit of Prime Minister Mohammad Khan Junejo. Last year the United States signed a similar memorandum of understanding with India during Mr Rajiv Gandhi's trip to Washington. The Indian agreement has far greater economic significance than that being worked out with Pakistan. Trade with India amounts to approximately \$1,600 million per year, according to Commerce Department figures, and something like \$75 million of that is in high technology equipment, including computers.

By contrast, trade with Pakistan amounts to only \$350-400 million per year, with most of that consisting of aircraft, soya bean oil and heavy industrial equipment. According to a Commerce Department official, Pakistan is just beginning to automate its government, and with no domestic computer industry it will have to import everything it needs.

But the real significance of the Pakistan agreement may be political. Ken Flamm, a research associate at the Brookings Institution in Washington, says that the trade agreement will smoothe the Pakistani feathers, ruffled by the lack of an arrangement such as that already offered to India. At the same time it will give the United States some control over the way in which the high technology equipment is

The United States is primarily worried that Pakistan might use computers obtained under the agreement to further a nuclear weapons programme. While the United States does not believe that Pakistan now possesses nuclear weapons, if takes the view that Pakistan could produce such weapons in a fairly short space of time. Prime Minister June to took some pains during his visit to emphasize the peaceful nature of Pakistan's nuclear programme. A joint statement issued by the two governments affirmed the Prime Minister's support of "US efforts to promote arms control and the non-proliferation of nuclear weapons". Joseph Palca **AIDS**

Confused ethics of blood testing

Will the publication this month of the results of compulsory blood tests for the acquired immune deficiency syndrome (AIDS) virus in potential military recruits in the United States has provided valuable, and to some extent disturbing, information on the spread of the virus, monitoring attempts in Britain are foundering on ethical and bureacratic rocks,

According to Sir Richard Doll, who has been asked by the British Medical Research Council to try to overcome the problems, all concerned are agreed that it would be unethical to take blood specifically for AIDS testing without informing those being tested of the purpose and result of the test. But the contentious question is whether the testing of blood samples taken for completely different purposes should be allowed.

Those who argue against such tests do so on the grounds that it would be unethical not to pass on the result of positive tests to the individuals concerned and yet unethical also to inform them because of the lack of prior consent. Those for whom the need to monitor the spread of the virus is paramount advocate that tests are carried out in an anonymous way so that it would be literally impossible to identify the individual that provided the blood sample. The justification for brushing the ethical problem under the carpet is that without information on the spread of the virus, it will be hard to persuade those at risk, including politicians, of the need for preventive measures.

As sexual transmission is the only way by which the virus can spread in the general population, it is necessary only to monitor blood samples from sexually active groups. One obvious source of such samples for anonymous testing would be antenatal clinics, but the Royal College of Obstetricians and Gynaecologists has objected to the idea. Another source being investigated is sexually-transmitted disease clinics, which have the advantage of including both sexes.

At present, the compulsory tests on potential blood donors provide the only source of information on the spread of the AIDS virus in the British population at large. Among 140,000 potential new donors tested between February and May this year, 7 individuals (or 0.05 per thousand) had a positive test. From October 1985, when the testing began, until May 1986, the rate was 0.02 per thousand but it is impossible to determine the rate per donor, according to Dr Harold Gunson, who collates the figures, because a substantial but unknown number of donors have given blood on more than one occasion during that period.

Prevalence among new donors is the

best figure to monitor for a trend but none is yet discernible, says Gunson, who is in the process of determining the sex and age distribution of the donor pool so that prevalences can also be worked out on that basis. The overall prevalence among UK blood donors is about 20-fold less than it was in August 1985 in the United States, the latest period for which figures are available.

The UK Ministry of Defence is opposed to the compulsory testing of potential military recruits. But in the United States that source has provided valuable figures on the prevalence of the virus in a sexually active heterosexual population.

Figures published in the 4 July Morbidity and Mortality Weekly Report show that the overall prevalence from October

1985 to March 1986 was 1.4 per thousand Figures varied widely by region and age group, ranging from 0.2 to 10.1 per thousand. The latter figure was for those of 26 or more in the central states on the Atlantic seaboard. At last month's huge AIDS conference in Paris, a figure of 20 per thousand was given for 18-25 year old recruits from Manhattan. Just over 300,000 potential recruits have been tested overall, with 459 positive results. The prevalence rate in males was three times that of females.

Seropositive applicants are excluded from military service, illustrating the growing discrimination that discourages people from agreeing to be tested and physicians from the prospect of having to inform anyone who has not specifically agreed to be tested of a positive result. Exclusion from life insurance and the possibility of losing one's job are added discouragements. **Peter Newmark**

Japan

Islanders put environment first

JAPAN'S Liberal Democratic Party (LDP) won a landslide victory throughout Japan in the double election on 6 July, except in Miyakejima, a tiny Pacific Island south of Tokyo, where the party suffered a crushing setback. Local and worldwide opposition from environmentalists to government plans to build a US military airfield on the island probably helped to sway

Miyakejima is an idyllic volcanic isle blessed with coral reefs, luxuriant tropical vegetation and two rare endemic species of bird, the Izu Island thrush (Turdus celaenops) and Ijima's willow warbler (Phylloscops ijimae). But if military planners have their way, the island will become an "aircraft carrier" for US Navy warplanes to practice night landing.

The local islanders, however, have put up dogged resistance to the government's plan. All attempts by the Defense Agency to hold public hearings on the issue have failed and two island assemblymen have been threatened with recall for failing to voice their opposition to the airfield. In the general election the Japan Socialist Party won easily over LDP with a vote double that of the previous election. International support for the islanders cause has grown rapidly and they can now count British royalty amongst their allies.

In late May, the Wild Bird Society of Japan reported that the Duke of Edinburgh, president of the World Wildlife Fund, had written to Prime Minister Yasuhiro Nakasone and the US Department of Defense appealing for the plan to be called off to protect wildlife in the island. Following this the International Council for Bird Preservation passed a resolution in June opposing the airfield's construction.

The Environment Agency carried out a survey in the area of the planned construction after a volcanic eruption in 1983 and concluded that "artificial objects would destroy the area if put up in defiance with harmony of the scenery". But the agency has yet to clarify its official position.

Numerous LDP delegations have visited the island to try and woo the islanders with promises of investment. But to no avail. As one islander put it: "important people from the LDP say they will make the island a 'mountain of treasure' but the island is already a mountain of treasures"

David Swinbanks

More dead penguins

THE mysterious mortality of rockhopper and gentoo penguins observed in the Falkland Islands (see Nature 322, 4; 1986) has now spread to Argentina. But the Argentine National Atomic Energy Commission (CNEA) has ruled out the possibility, suggested at a press conference at the Soviet Embassy in Buenos Aires, that radioactivity is involved. According to the Soviets. the four British ships sunk during the 1982 Falklands conflict had been carrying nuclear weapons, the casings of which had leaked, contaminating the waters. The CNEA scientists, however, are preserving a proper academic detachment on the issue. Asked to comment on the deaths of some 300 penguins near Piero Deseado, they stated categorically that, even if some radioactive material had escaped into the sea, the concentration would have been far too low to be dangerous. Vera Rich

Engineered organisms

Confusion over European rules

THE announcement this week of a new and supposedly safe vaccine against rabies (see pages 304 and 373) may bring to a head a simmering conflict in Europe over whether to permit the release of genetically engineered organisms.

The new vaccine is a version of the vaccinia virus, which is related to smallpox but much less dangerous, engineered to express a protein from the coat of the rabies virus, and thus create immunity in any creature inoculated with the vaccine. Target populations are foxes in Europe and raccoons on the east coast of the United States. Both, in principle, could be fed the vaccine in infected bait.

Developed by the French genetic engineering company Transgène in Strasbourg, the vaccine will be commercialized by Mérieux of Lyons, where chief scientist Philippe Desmettre said last week that there are no immediate plans for field trials. French regulations require approval of such trials by the ministries of health and agriculture, but Mérieux has not so far applied for permission. The company has supplied vaccine for tests by the Wistar Institute in Philadelphia, but use of the vaccine in the wild is likely to take place in Europe first, said Desmettre

In Europe, there is no general agreement on how to regulate field trials. Denmark has jumped the gun and already imposed controls; in West Germany and

in the European Parliament, the Green Party is pressing for action to prevent the release of genetically engineered organisms, but in Britain, France, the Netherlands and elsewhere there seems little concern. In the midst of this confusion, the European Commission is attempting to create a little order rather than see yet another European market divided by multifarious regulations. But the Commission itself is a house divided, with those representing scientific, industrial and agricultural interests in conflict with the environment directorate.

Nevertheless, Commission officials said last week that a paper on the problem is now circulating and is likely to be presented to the European Council of Ministers towards the end of this month. This, however, would merely alert ministers that there is an issue to be discussed and it is not even clear at what council the issue would be thrashed out. The European Parliament, whose irritant value — if not real power — is steadily increasing in the European pantheon, will debate a hardhitting report on the same issues by Dutch socialist Phili Viehoff, later this year. Not only will Viehoff present her report, but six other committees covering biotechnology and the environment will also table positions, leading to what could be an acrimonious debate.

The Commission itself is aiming to sub-

mit joint safety proposals to Council by April next year — Denmark's "banning" of the release of engineered organisms, hailed as a success by Europe's greens, is not a major obstacle, for trials are not truly "banned" although they must be referred to the government for approval.

In the next few weeks, a major report should appear by the Organisation for Economic Cooperation and Development (OECD) in Paris on "safety considerations in the use of recombinant DNA". It is said by those who have seen it to be a "very reassuring report", arguing that risks are small. Britain is expected to base its own guidelines on the OECD recommendations.

Robert Walgate

Chinese science

Back to your work units

CHINA is to introduce new rules on foreign study. Although the number of people sent abroad to study at government expense is to remain at its present level, the mix will be different. There will be more emphasis on those applied disciplines necessary for China's modernization programme, and less opportunity for students to go abroad immediately after completing their first degrees. On the other hand, the number of people with masters' degrees who go abroad to work for a doctorate will be increased. Students who go abroad at their own expense (mainly the children of top officials, plus the lucky few who have wealthy relatives abroad) will be given greater "guidance" to ensure that their chosen studies also conform with the state plan.

The changes are meant to ensure a sufficient supply of trained personnel to satisfy the demands of "work units" throughout the country. "Poaching" of graduates from their assigned jobs is now a problem in China. Understaffed enterprises frequently offer substantial and fringe benefits to well-trained recruits; they even advertise in newsletters which flourish in spite of official disapproval. The new rules should frustrate the "poachers". From this year onward, most of the quotas for government-sponsored students will be assigned to enterprises and work units in need of trained staff; the latter will then select who is to go abroad.

Foreign study, it is stressed, is not meant to be simply a means of self-betterment. Those who obtain a doctoral degree abroad will not now be permitted to stay on just to acquire a still higher qualification. Instead, they will have to return to an appropriate job in China for several years, before being sent abroad again. This, it is explained, will better help them coordinate their studies with China's needs.

Space antiques hedge against inflation

Washington

"MUSEUM piece" is an apt term for a satellite the US Air Force plans to launch next October. Although it is now called the Polar Beacon Experiment and Auroral Research (Polar BEAR) satellite, for eight years it hung in the Smithsonian Institution's National Air and Space Museum in Washington as a Transit 5A, an example of an early navigational satellite.

The satellite's transformation came at the hands of the Johns Hopkins University Applied Physics Laboratory (APL) in Laurel, Maryland. APL, the contractor for Polar BEAR, realized that the satellite shared many components with the Transit 5A and Oscar satellites it had built in the 1960s and early 1970s for the Air Force. In 1975, the Smithsonian was looking for an example of an early navigational satellite to hang in its new museum. APL offered an Oscar 17, with flight-tested components, that was made to look like the earlier Transit 5A. To get its Oscar satellite back, APL offered the Air and Space Museum an untested back-up Transit 5A satellite that had been on display at APL. By using the older parts, a saving of about \$2 million was

achieved on the \$15 million bill for the satellite. Much of the saving came from the solar panels. All but one of the thousands of solar cells on the panels worked perfectly when APL tested them.

A Scout launch vehicle will carry the Polar BEAR satellite into a circular polar orbit from Vandenberg Air Force Base in California. The Air Force will use the satellite for experiments to improve communications over the poles. In addition, an Auroral Imaging Remote Sensor will study the aurora borealis.

This is not the first time that the Air and Space Museum has transferred an exhibition piece to active duty. The University of Iowa borrowed part of the attitude control system on the museum's Applications Technology Satellite for its Plasma Diagnostic Package that flew aboard Spacelab 2 on the shuttle last summer. A foot restraint system, once used on Skylab and donated by the National Aeronautics and Space Administration (NASA) to the museum was used by shuttle astronauts. NASA also borrowed Skylab's shower, but only for developmental studies for the manned Joseph Palca Space Station.

OECD indicators

Science statistics prove slippery

RESULTS for 1983 and data for a few countries for 1984–85 suggest a "definite slowing down" of research and development spending in the industrialized countries, according to the latest "science and technology indicators" report* by the Organisation for Economic Cooperation and Development (OECD).

Some doubts remain about the figures. The rate at which data are accumulated, checked and reported by governments means that most data in the OECD tables end in 1983 and the latest trends are hard to spot. Between 1979 and 1983, research and development expenditure in the OECD states (most of the non-Communist industrial world from the United States to Japan) had been rising rapidly.

Other points made by the OECD study are that up to 1983:

Research and development became

Getting tough on doctorates

How to make do with little might be thought of as the theme of the new corporate plan from Britain's Economic and Social Research Council. Taking inflation into account, the £23.6 million budget is lower than it has been for a decade and ways have to be found to be more selective.

The major move is to take £2 million from the budget for postgraduate awards and shift it to research over the next five years. The shift is largely dictated by complaints over the appalling performance of doctoral students supported by the council. Only 20 per cent of students submit theses within four years and around half never write up their research at all.

The council is now to take a tough stand. Institutions where fewer than 10 per cent of students submit theses within four years will be banned from taking on new students for two years. By 1989, 60 per cent of students must submit theses before new funds will be awarded. No action is planned against individual students: supervisors are to be held responsible. One hundred studentships will go over the next two years.

More money is to go into research but the council is to tighten the reins. Expenditure is to be concentrated on "research initiatives" where the council determines what will be done rather than on research grants where researchers choose for themselves. While this gives some assurance of the quality of research, it does, as the plan points out, lessen the chances of throwing up "original ideas with high future value". Economic and social charge in contemporary Britain is the current key research area.

Alun Anderson

more concentrated in the largest countries.

- Japanese research and development grew faster than that in any other country.
- The United States remained the largest research performer, with the countries of the European Economic Community (EEC) second.
- Japan spent "substantially less" than the EEC countries in total.
- Research and development kept pace with or exceeded economic growth in most countries. Exceptions are Switzerland, Australia and the United Kingdom during 1981–83.
- Most OECD government funding went to defence and space programmes.
- Basic research received about 15 per cent of total OECD research and development funds in 1981.
- Industry increased its role in relation to government as a research and development spender, exept in Switzerland.

The value of OECD's figures on higher education research is questionable, however, according to a British research team which has just reported to the British Advisory Board to the Research Councils (ABRC). The report will not be published until the autumn, but its authors have indicated that OECD data are limited by their reliance on national government interpretations of the "Frascati agreement" of the 1960s, which was supposed to codify the reporting and comparison of national research statistics but has since lost its real effectiveness due to changes in institutional structures. Governments may also stretch the meanings of terms to suit their political convenience.

Some of the more glaring problems thrown up by the British work, which relates only to higher education, are in the varying definition of universities, and the attributions of government laboratory spending. Japan, apparently, attributes half of the total budgets (including salaries) of its 1,000 or so colleges, few of which are at full university level, to "research"; and the United States lumps the research of its big defence laboratories such as Lawrence Livermore and Los Alamos in with that of the universities. In the DM 20,000 million German university accounts DM 5,000 million is distributed in part as research, but turns out on analysis to be income from hospital beds, through certain medical universities' private health schemes.

The most anomalous of the six countries analysed by the British group is Japan, but European countries as a whole also suffer in a major way by excluding all international research facilities (such as the Organisation for European Nuclear Research, CERN) from their higher educa-

tion statistics. (The United States, by contrast, includes its big science facilities such as Fermilab in its university figures.)

Altogether, the feeling in British science policy circles is that such anomalies allow the all-powerful Treasury to decry OECD figures which show declining research spending in Britain. That is why an independent, in-depth study was commissioned. It is believed to leave no escape from the conclusion that British research in the higher education sector has indeed been undergoing a relative decline — which is what, of course, everyone knew but could not prove.

Robert Walgate

Academician's Berlin arrest riddle

A PUZZLING diplomatic incident involving East and West Germany was resolved on Monday, when the West German authorities decided it would not be in the public interest to prefer charges against Professor Herbert Meissner, deputy general secretary of the East German Academy of Sciences.

Meissner had been on what the East Germans described as a routine business trip to West Berlin, travelling on a diplomatic passport, when he was arrested for shop-lifting. He was subsequently taken to Munich where he was questioned by BND, the West German intelligence service. He then, in some unexplained way, appeared in Bonn, at the East German permanent mission. The head of the mission, Herr Lothar Glienke, then lodged a strong protest at the West German Chancellor's office.

According to Glienke, the charges against Meissner were totally fabricated, his journey to Munich was "abduction", and his interview with BND had included the use of pressure and blackmail to try to make him betray his country. Glienke had therefore demanded an immediate guarantee from the chancellor's office that Meissner would be able to return to East Germany immediately, and that his diplomatic passport and personal papers would be returned.

The West Germans, however, maintain that the shoplifting charge was genuine, and that instead of answering the questions of the West German police, Meissner had demanded to be taken to BND in Munich, saying that he wanted to defect. A spokesman for the West German government, Herr Friedhelm Ost, stated, moreover, that Meissner combined his duties for the academy with work for the East German Ministry of State Security.

Either explanation of Meissner's movements last week leaves a number of questions unanswered. The West German decision to drop charges will, however, presumably bury these questions in diplomatic obscurity. Vera Rich

UK universities

Research gradings stir emotions

British university departments that received poor marks in the recent University Grants Committee (UGC)'s assessment of research may have a chance to be re-rated if they can do better. Sir Peter Swinnerton-Dyer, chairman of UGC, spoke of the need for machinery to pick up those that improve "dramatically" in giving evidence to the House of Lords Select Committee on Science and Technology last week. But no general reassessment is expected for 4–5 years and 15 per cent of the money available to the universities is now to be distributed according to the quality of research.

The assessment has provoked considerable outrage. Departmental groups have been rated as below average, average, above average or "starred" — of outstanding merit by international standards. But angry academics writing to *The Times* describe the assessment as "wholly lacking in intellectual credibility" and its methodology as "questionable", "extremely crude" and "seriously defective".

Many researchers even protest that they have been given no indication of how the ratings were arrived at. But the method was actually straightforward: "individual judgement helped by some factual records", as a member of UGC put it. Last year, a letter was sent to all universities requesting short (500-600 word) profiles of their departmental "cost centres" together with a list of five recent publications demonstrating the quality of research in each cost centre. Cost centres are larger units than departments: mathematics and chemistry have their own cost centres, but the biological sciences are divided into biochemistry and "other biological sciences", and the physical sciences into physics and "other physical sciences".

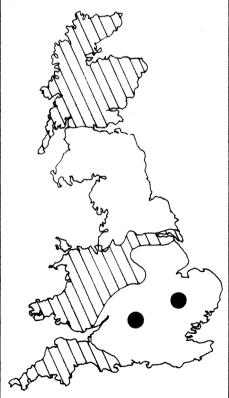

UGC's committees (for physics, biology, and so on), each with some 12-15 members then divided up into smaller subcommittees and parcelled out the replies. Further evidence was added: the number of grants and research studentships gained from the research councils over the past three years, the level of support from the large medical charities, the numbers of Royal Society fellowships held, "new blood" posts gained over the past three years and money gained from industry. Opinions were sought and meetings convened with the research councils which gave their private rather than corporate views.

At the end of this first stage, cost centres were scored on a scale of 1 to 5; where there were many departments in one cost centre (zoology, genetics and biology are all "other biological sciences"), some subcommittees scored individual departments. Final adjustments were made at

meetings of whole committees where personal knowledge of outstanding researchers, or those that had slipped from their prime, counted for much. It was then decided not to mention specifically the below-average departments, nor to say how below average they were, but to issue just three ratings and the "stars".

Given the way the assessment was done, huge surprises cannot be expected; en masse the results confirm popular prejudice (see map). In the celtic north and west and parts of the Midlands, below-average cost centres are in the majority, often by a very considerable margin. London (with a few exceptions), the south and north of England and Edinburgh and Glasgow are in the black. Towering above all are Oxford and Cambridge, the latter with a staggering 32 starred departments and none below average.

But it is not all so simple. Even universities with poor overall ratings may contain departments of excellence — Dundee with stars for biochemistry and applied mathematics for example. Do these indicate a few individuals' outstanding efforts? And there are whole universities which go against trends. Warwick had seven stars

In the hatched areas universities have less than one above average cost centre for each one below average; at the two black dots (Oxford and Cambridge) there are nineteen or more above average for each below average; in other areas the ratio varies from one to ten above average (University of Warwick) to below average.

and no below-average departments: does this suggest others might learn from its management?

Critics, on the other hand, would say that nothing useful can be gained from the assessment. The chief objection is that it was grossly unfair to look at cost centres rather than individual departments. Several different departments often had to share a single report and pool the five examples of their recent work, so that some researchers went virtually unrepresented. The problem is most severe for small arts departments where, as one historian put it, research on Ancient Greece, might be judged from a work on modern Europe.

Sir Peter Swinnerton-Dyer agrees that the assessment results have not been "perfect" here. Small departments may also have been penalized because there seems to have been little effort to look at productivity per staff member rather than a few examples of excellence. Science Citation Index, with weighting for quality of the journal cited, might have provided a database.

Another criticism is that the style of a university has not been taken into account. Salford, for example, scores rather poorly but has been held up by British Prime Minister Mrs Margaret Thatcher as a model university for its success in creating jobs. A cut in funding because it fails to reach certain research norms may be regarded as an implicit judgement of its aims. Other university departments simply feel they have been wholly misjudged — and can provide evidence that they should be rated differently. But no general appeal mechanism is planned.

Perhaps the most telling criticisms of the assessment are of the effect it may have. What made the assessment necessary is that funds need to be concentrated on research that will prove outstanding. A monolithic judgement may not do this but simply fulfil its own prophecies. Departments that have, in the past, been poorly funded by the research councils are likely to have gained poor ratings and will now find life even more difficult as they lose UGC funds. The judgement of UGC may make it harder for them to find funds from other sources too.

But, if it is original ideas that should be funded, it can be argued that the more independent sources of funds there are the better. How will poorly rated departments, among them those that contain a few excellent people, now get back on their feet? Sir Peter advised that universities should continue to fund the good and pick out for help those that can improve. He saw little to be gained by putting money into bad departments. Harsh advice perhaps, but the chairman of UGC knows, perhaps better than anyone, how little money there is to spare for university research. Alun Anderson

SDI

UK scientists should take care

British scientists thinking of participating in Strategic Defense Initiative (SDI) research might do well to consider their legal position carefully. An incident in the United States in which basic research results were suddenly classified and what has recently become known about British Ministry of Defence (MoD) guidelines suggest that scientists may find it hard to protect their rights of free publication.

The terms of British involvement in SDI are enshrined in a memorandum of understanding between the British and United States governments. A research contract is placed by the SDI Organization (SDIO) in Washington, an office separate from the Pentagon, in one of five classified, military Project Areas, or in the \$100 million Innovative Science and Technology (IST) programme for basic science.

Exactly what regulations cover the latter programme are unclear. The SDI Participation Office in the MoD promises scientists the right to publish work that is also receiving SDI funding, with the provision that a copy of the paper of presentation is delivered to it and SDIO in Washington before publication.

Fundamental research will thus be free, as has often been claimed by the university liaison officer of the Ministry of Defence SDI office, George Gallagher Daggitt. But will this always be true? In response to a letter from Paul Labbett (8 April 1986), research contracts officer at Imperial College, London, Daggitt wrote: "It is however conceivable that exceptions to this rule could arise if there is the likelihood of disclosing operational capabilities and performance characteristics of developing military systems. In this case the contract for the work will clearly stipulate that responsibility for the release of information lies with the sponsoring office" (that is, SDIO in Washington).

The case of a US high-energy physicist, Dr Andrew Sessler, shows that successful SDI research can easily be classified. His team's work on the free electron laser was guaranteed open for publication until he showed how gigawatt power outputs were possible in March 1985. SDIO immediately classified the entire experiment and the results. The work, largely paid for by the Department of Energy, was part of the civil fusion reactor programme. But as Sessler took a small grant from SDIO it became the sponsor. The work was classified top secret (Sessler and his staff were threatened with expulsion and jail if they released details) for 13 months until April this year, when the results alone were de-classified. The experimental details are still classified.

SDIO is free to classify what it sees fit. The memorandum can offer no guarantees that fundamental science will be open for publication. MoD Guidelines say a review procedure is available "so that appropriate representations can be made". But SDIO in Washington has the final say. A significant number of British scientists have applied for funding under IST: there are 36 individual proposals, and 2 consortia.

The memorandum embodies the principle that there will be no guaranteed work although the figure of \$1,500 million was floated early on. Days before the memorandum of understanding was signed, the British draft contained a schedule of work in three categories: commercial work from research into manufacture worth \$1,000 million, government contracts for research worth \$250 million and university research up to \$250 million. How much will British companies and individual researchers actually gain in SD1? From \$50 to \$100 million in total, estimates MoD.

MoD can identify five commercial contracts worth a total of \$1 million. Another 12 contracts are in negotiation, each worth around \$2 million. The first round of IST proposals might bring another \$10 million. Government-to-government business could rise from the present \$15 million to \$50 million.

The government agreed a special research contract for the work in which it is the principal or subcontractor. The Letter of Offer and Acceptance negoti-

ated to cover the first two contracts, "written according to patent law" according to the SDI Office in the MoD, acts as a standard contract for SDI research and is said to safeguard the rights of ownership of technology. The letter is secret and applies only to government work. Yet it is said to embody the best definition of intellectual property right, and to safeguard technology produced in SDI for the researcher concerned.

Why should it be secret? And why cannot other researchers use the definition of intellectual property right? MoD says it is for private individuals and companies to get the best deal they can for themselves even though the memorandum of understanding was intended to act as an umbrella agreement for all participants. The Americans insisted on this arrangement.

Government work can only be research, not manufacture, and must stay within the terms of the 1972 Anti-Ballistic Missile (ABM) Treaty according to the memorandum of understanding.

A joint MoD/Foreign Office Arms Control Unit has a veto on government research proposals that threaten to stray beyond other treaty obligations. If a British company were to design, prototype, test or build a component of SDI, however, it is unclear in the memorandum whether or not such proposals could be vetoed.

The right to own technology originating in a research contract funded either by SDIO (as basic science), or in a subcontract with a US company (on project work), is not defined in the memorandum. This is thought to have contributed to the

UK star wars consortium launched

A CONSORTIUM of eleven UK defence contractors has bid jointly for the first Strategic Defense Initiative (SDI) contract worth \$9.9 million, the European Architecture Study, let to the Ministry of Defence by the Strategic Defense Initiative Organization (SDIO) in Washington, DC.

Ian Sutherland, a director of Marconi, said that this "team" will share out research work if it secures the entire study and would work together as "UK Ltd" on the SDI contracts that follow on. These could be worth tens of millions of dollars.

The group includes defence contractors GEC-Marconi, British Aerospace, Barr & Stroud and Shorts, electronics companies Thorn EMI, Racal and Ferranti, the Royal Ordnance Factory, and computer software houses CAP Scientific, Scicon and Software Sciences.

The architecture study will consider how an SDI system could operate in Europe. Four subcontracts will be awarded, probably in September, in computer systems, weapons, battle management and command, control and communication. Few contracts have yet been awarded to British companies. Sutherland said Marconi has sold "£4 million worth of hardware", including exotic electronic components such as thyratrons (which switch very high currents quickly) and silicon-on-sapphire semiconductors (which are relatively unaffected by radiation). In addition, Marconi Projects has two research subcontracts worth under \$250,000.

Up to 12 other proposals are in the pipeline, including those for electromagnetic guns, battle management, lethality and target hardening, very high speed integrated circuits, high-energy lasers, advanced sensors and particle beams.

SDIO in Washington has also requested access to the Ministry of Defence's results from the Teal Ruby experiment which considered strategic defence from short-range and mid-range missile attack. But the Australian government, which collaborated in the experiment, is set against SDI participation and Australian permission is necessary before results can be released.

Paul Walton

low take-up of work by companies. Background research, that is existing company data on intellectual property rights defined by patent or copyright, can be protected. But foreground research, that produced during a funded contract, is not protected by the memorandum.

As things stand, a US prime contractor would be legally entitled (under US law) to patent foreground research, denying use to the originator for 17 years. This patent defines the owner as the body which pays, not the individual or organization which completes the research.

A further problem for British researchers is that the memorandum does not waive those items of US law, in particular the Export Administration Act, that make

At least we've proved the existence of Black Holes ...

it difficult for items of technology or technical data in the form of proposals or descriptions to be passed freely between Britain and the United States.

Technology transfer law still applies to SDI work. "Both Governments will make every effort to process within 30 days requests for export licences for technical data packages or other controlled information for direct bidding", according to the memorandum. In practice, clearance can take several months, by which time an SDI contract will have been let. Visits to secure sites, to closed conferences, or to discuss classified information with a partner in the United States requires prior clearance, and full vetting, of any person by the US authorities. It is likely that positive vetting will be carried out by US embassy staff in the United Kingdom. Most British citizens will be required to sign the Official Secrets Act.

The memorandum is "secret in perpituity", or top secret. A full debate on British participation has been requested by Labour MP Tam Dalyell but denied on the basis that the United Kingdom has negotiated a good deal which the United States does not wish other allies to know of in detail. All the UK opposition parties, Labour, Liberal and Social Democrats, have pledged that they will do away with the memorandum and pull out of SDI.

Paul Walton

US space

Shuttle faces more delay

Washington

THE US National Aeronautics and Space Administration (NASA) announced last week that shuttle flights will not now resume before 1988, despite earlier estimates that the shuttle might fly again as soon as next summer. Although disappointing, the delay, say NASA officials, is necessary to complete a review of the design and testing of the solid rocket motors (SRMs) responsible for last January's shuttle accident.

In a report requested by President Reagan, NASA spelled out its plans for implementing the recommendation of the Rogers Commission on the accident (see Nature 321, 637; 1986). NASA hopes to redesign the SRMs so that existing hardware can be used, but there are alternatives using completely new hardware in case that plan is frustrated. At NASA's request, the National Research Council (NRC) has established an independent oversight group, chaired by H. Guyford Stever, to superintend the redesign.

Other hardware modifications recommended by the Rogers Commission included improvements in the tyre, brake and nose-wheel steering systems. NASA says that some of those improvements were under way at the time of the accident, and that the other modifications are in hand. Until the improvements are judged a success, the shuttle will continue to land at Edwards Air Force Base in California, where there is a longer landing strip. Ultimately NASA hopes to land shuttles at the Kennedy Space Center in Florida where they are launched. NASA also plans a thorough review of all critical safety items on the shuttle, and a second NRC oversight panel is being formed to watch over that process as well. Not surprisingly, safety issues are uppermost in the minds of most NASA officials. Waivers allowing marginal parts to be used in launches will be few and far between, says one NASA official.

NASA has also begun two separate reviews of its much criticized management practices. One will look at the shuttle programme, the other at NASA as a whole. Many at NASA involved in the shuttle have either left the agency or been transferred since the accident. The latest casualty is Lawrence Mulloy, director of the SRM programme at the beginning of the year, who resigned last week after having been transferred from that programme.

NASA has yet to make a final decision about crew escape systems, but preliminary conclusions suggest that no approach will provide a safe escape route under all conditions. But further attention is to be paid to procedures for aborting launches, including one scheme for transatlantic escape.

The Rogers Commission pointed out that total reliance on the shuttle for launches had put heavy pressure on NASA to increase its launch rate: NASA hopes that the pressure will be partly reduced by the new policies it has adopted on the choice of cargo for the shuttle bay, but it is also now backing the claims of other agencies that there should be a mixed fleet of launch vehicles, including expendable rockets. Responding to a request from Congress, NASA has asked NRC to form a third panel that will evaluate launch rates and the balance between manned and unmanned launch systems. Edward David, president of Exxon Research and Engineering Company, will chair this committee

Joseph Palca

Now it's save French science!

FRENCH scientists appear to be getting more and more like their British colleagues — absolutely desperate. But in one way the French are going further. Discovering that appeals to their own government over recent cuts have failed (no doubt in part because, as it is said, the new science minister is uninterested in politics), they have gone to the lengths of producing an international petition: "Save CNRS" (the principal French research council).

"We the undersigned members of the international scientific community", the petition reads, "wish to express our grave concern regarding the policy followed by the French government. The policy has already resulted in: budget cuts (more than FF 4,000 million — £400 million); 25 per cent reductions in new posts for 1986; a

decision to cut the number of scientists employed by government in 1987; the smallest ratio of research spending to gross national product in the West; and the suppression of the CNRS Comité National." The Comité is a decision-making body whose loss brings to a standstill the whole administrative machinery of the CNRS—including the setting up of new posts and grants.

The petition calls for the French government to reinstate the Comité National, and reverse the new downward trend in jobs and cash for French science. What it fails to do, however, is to give an address to which to send the completed petition. But interested readers could always try the French Prime Minister, Jacques Chirac, at the Matignon... Robert Walgate

European research priorities

SIR-The Advisory Subgroup on Human Reproduction of the European Medical Research Council (EMRC)* has published recommendations for research related to in vitro fertilization and embryo transfer and has sought to identify priority areas in human reproduction research deemed particularly suitable for investigation by European scientists2

The subgroup has noted the decrease of financial support for human reproduction research, particularly in the development of new and safe methods for fertility regulation, from both the public and private sectors'. This contrasts strikingly with the recommendations for increased support for reproduction research by all sectors called for by 146 governments at the International Population conference in Mexico City in 1984, where particular emphasis was placed on the special needs of developing countries4.

The subgroup believes that the scientific community has a particular contribution to make to research on new methods for fertility regulation for three reasons: its well-established record in this field, its long-standing tradition of providing medical and scientific assistance to developing countries and the close collaboration between its medical research councils and the European pharmaceutical industry.

In order to facilitate this collaboration, the subgroup held a consultation with representatives of interested European pharmaceutical companies in October 1985. At a meeting of the subgroup alone in April 1986, the following recommendations, which represent the views of the subgroup and do not necessarily reflect the views of the industry participants in the earlier consultation, were drawn up.

- (1) Steps should be taken, separately and jointly, by both industry and the medical research councils to increase the priority given to research on new methods of fertility regulation and on related fundamental research.
- (2) The requirements for clinical trials of new contraceptive drugs and for the approval of such drugs for public use vary from country to country and are deemed unnecessarily complex in certain instances. The subgroup recommends that these requirements be modernized and standardized.
- (3) A marked increase in the number and magnitude of liability lawsuits has caused some companies to withdraw from the fertility regulation field, and is one of the primary reasons for decreased work in this field. The subgroup recommends that European MRCs and industry representatives should work together to forestall this problem which threatens progress in this
- (4) In view of the challenges confronting

science to develop new methods of fertility regulation, the subgroup recommends consideration of the establishment of a European funding mechanism for reproduction research, sponsored and funded by industry and the MRCs and dedicated to the support of European research and research training adapted to the jointly derived requirements of both the private and public sectors.

Henderson Island

SIR-In 1983 there was international concern when a strip-miner from West Virginia proposed to establish a settlement on Henderson Island in the Pitcairn group of the central South Pacific, as it was thought to be one of the few raised atolls still comparatively unaffected by human activity1. As much of the case for preserving the island depends upon its undisturbed state. we are now concerned to observe a statement in an influential journal that: "The recent discovery of several Polynesian occupational sites on Henderson' shows that the island had, in fact, been inhabited in prehistoric times. On the basis of vertebrate remains from one of these sites we can now show that this period of human occupancy was accompanied by extinction and a consequent decrease in the species diversity of the island... The biota of Henderson Island can thus no longer be regarded as being in an unaltered state."3

As this statement is liable to be quoted in support of further proposals for development of Henderson Island, it deserves some scrutiny.

The past Polynesian presence, which was already noted in our recent contribution on the birds of the island, had so little impact that it is difficult to detect. Its only observed effects appear to have been the

introduction of the Polynesian rat Rattus exulans, and perhaps some plants, and the possible extermination of some widespread but unobtrusive seabirds, whose survival may have been overlooked, and pigeons of the genus Ducula, attributed to two species because the wings were comparatively small whereas the jaw and legs were rather large.

The alternative possibility that instead of two additional species of pigeon occurring on one very small island alongside the small one which still survives, the pigeon bones may have belonged to a single large species showing the reduction in the wings common in insular birds, and also found in the flightless Henderson rail Porzana atra, which will be the next species at risk if the island is developed, is not discussed

The list of petrels of the genus Pterodroma reported to survive in the group3 does not agree with our experience⁴, and it is rather surprising that all the bones should be identified as P. alba when it is doubtful whether this is distinguishable osteologically from one of the other species which is now commoner, P. arminjoniana.

It is to be hoped that this contribution will not be allowed to count against the case for preserving the island, which is apparently still at risk.

More bright ideas

SIR-We read with interest of Greg Ojakangas's award-winning proposal to use a ROOPH (Readily Operative Overhead Protection by Hippos) in the event of nuclear attack (*Nature* 321, 373; 1986).

We wish to suggest the use of BOOBS (Blockade of Overhead Objects by Baby Seals) based on the same principle.

Canada could supply the animals (having an abundance of baby seals, especially in recent years) in return for protection. Use of an indigenous species has strategic and financial advantages, and, unlike hippos, baby seals are already cold-adapted for deployment at high altitudes or in winter (nuclear or otherwise).

Gentle warning on fractal fashions

The novel idea that fractal structures can support high-energy lattice vibrations may not be the philosophers' stone that some have suggested.

FRACTAL structures are understandably one of the captivating fashions of our times. Even without the proselytizing of B.b. Mandelbrot (as in The Fractal Geometry of Nature (Freeman, New York; 1983)), the subject would by now have been dragged into prominence by the host of practical applications to which it lends itself. The simplest problems are those of the aggregation of particles onto a growing aggregate, where there is now a host of demonstrations that the density of such a structure is a decreasing function of its size, most graphically described by means of a "dimension" smaller than that of the space in which it grows. But it is plain that biological applications must also abound. For are not large polymer molecules put together by the aggregation of monomers onto a growing backbone candidate fractal structures?

This line of enquiry has already been productive. Some polymer structures do indeed turn out to be fractal structures, while the suspicion has grown up that the properties of some important biological molecules are in many ways a consequence of their supposed inherent fractal character. But fashions that are too pervasive can also be misleading, and require occasional correction. That is the chief interest in an elegant paper by J.A. Krumhansl (Phys. Rev. Lett 56, 2696; 1986) of Cornell University which, in the gentlest manner, warns people against the tendency to look for fractal explanations everywhere.

Krumhansl's topic is also interesting and potentially important. His startingpoint is a series of speculations about the interaction in molecules such as those of haemoglobin of the central iron atoms with the surrounding ring of porphyrin rings and the protein structures to which they are in turn attached. Changing the spin states of the central iron atoms requires a substantial amount of energy, greater than that corresponding to the mostly low-energy vibrations of the usual protein chain. So how can a larger amount of energy be exchanged with a protein environment? Fashionably, there seems recently to have been a tendency to invoke fractal phenomena of a new kind, those pertaining to the vibration of fractal structures of various kinds.

The mere idea that it might be possible to calculate the vibration frequencies of a fractal structure is naturally surprising. To be sure, it should in principle be possible

to deal with any specific fractal structure provided there is enough computer power to hand. One common model is that in which the particles in an aggregate are replaced by masses (all of the same size) which are then supposedly connected to their neighbours with springs with identical elastic properties. Since most simulations of fractal structures begin life on an underlying lattice with well-defined properties, solving the vibrational problem is essentially a calculation of the vibrations of a lattice in which there are patches missing. And even though each different arrangement of patches should in principle give rise to a distinctive set of vibration frequencies, the fact that the geometrical properties of aggregates can be described in gross terms (by their fractal geometry) means that it is reasonable to look for general properties of the vibrational spectrum of a fractal lattice.

It is nevertheless remarkable that so much has been accomplished in just over a decade. The frequency spectrum of a reasonably well-behaved solid (with three space dimension) is a function proportional to the square of the frequency. So much has been known since Debye and others took up the question of the specific heat of solids early in this century. At low frequencies, fractal structures have the same kind of vibrational spectrum; longer waves do not recognize that there are patches of the lattice missing.

The surprise (but a little thought will show that it is not really that surprising) is that the vibrational spectrum of a fractal structure includes a large proportion of high-frequency vibrations. Crudely, there must be within a fractal structure patches filled with particles which are nearly isolated from the rest of the structure, and which then perforce vibrate internally at lower frequencies because they are denied the opportunity for taking part in the large-scale long-wavelength vibrations involving the operation of the lattice as a whole.

This conclusion obviously neatly fills the bill required by the haemoglobin problems. If fractal structures not merely admit but require an unexpectedly large proportion of vibrations at high frequency (or, more strictly, short wavelength), there will be opportunities for the exchange of relatively large amounts of energy between, say, haem iron atoms and the surrounding haemoglobin molecule. But there is one snag: the peculiarly

fractal vibrations are also localized (to the patches of the lattice which are themselves almost geometrically isolated), so that the rate of energy exchange will not be great. Is it possible to circumvent that difficulty?

Krumhansl's paper is not so much a protest as a demurring. He does not question the possibility that fractal structures may sustain short wavelength vibrations (which, being cousins of more familiar photons, have inevitably been called fractons), but he does insist that the statement cannot be turned around in such a way that every solid with an anomalous vibration spectrum can be inferred to be a fractal structure of some kind.

The issue is of some importance because of the way in which estimates of the vibrational spectra of real solids (most simply made by measuring the specific heat as a function of temperature) have been used to make structural inferences. This has become especially fashionable in the study of amorphous solids, often said to be fractal over short distances. For starters, Krumhansl offers the example of the monatomic indubitably three-dimensional solid selenium, whose vibrational spectrum is as anomalous as it could be.

Krumhansl's explanation is both simpler and more persuasive. The anomalous vibrational frequency-spectra are often merely consequences of anisotropy of the forces between the atoms in a vibrating structure. Where proteins are concerned, for example, the forces are not central but are directed along the chemical bonds by which atoms are joined. And, in other circumstances, bond-bending forces become dominant.

The effect of Krumhansi's gentle broadside will not be to discourage interest in fractal structures. Quite possibly, the effect may be the reverse of that (no bad thing in itself). But this is an interesting case, which seems to happen more and more often, of how an explanation in search of a phenomenon may lay claim to far more territory than it can handle.

For the time being, and perhaps for a long time to come, progress in the field of fractals hangs crucially on numerical simulation. The results are convincing but not suggestive. They tend to confirm conjectures but not to suggest them. One day, it may all be different. Let us hope so.

John Maddox

Rabies control

Vaccination of wildlife reservoirs

from Roy M. Anderson

CERTAIN major infectious diseases of man and his livestock persist endemically in so-called reservoir populations of wild mammals. In Europe, two important examples are those of rabies and bovine tuberculosis. Such infections are usually difficult to control and past efforts have often centred on the widescale slaughter or culling of the reservoir host species in the absence of more effective measures. But in this issue (Blancou, J. et al. Nature 322, 373; 1986) the production of a recombinant vaccinia virus is described that may be an important step towards the control of rabies by vaccination.

Rabies, an acute viral infection of the central nervous system, has throughout human history been one of the most feared of all diseases because of the distressing clinical symptoms it induces and their invariably fatal outcome. The current epidemic in Europe (see figure) is characterized by a high incidence in the red fox (Vulpes vulpes), which accounts for more than 70 per cent of all reported cases, and populations of this species are believed to constitute the principal reservoir of infection. Tuberculosis in cattle (Mycobacterium bovis) is of less cause for concern to man but the infection can result in serious economic losses to the beef and dairy industries and it can present a threat to public health in the absence of milk pasteurization. In many regions of Western Europe populations of the badger (Meles meles) form an important wildlife reservoir of tuberculosis.

In both examples difficulties have been encountered in the design and implementation of effective control measures. A significant factor is the widespread public concern at the slaughter of wildlife for the control of diseases that are of limited significance to human health and welfare. Human deaths resulting from rabies in Europe, for example, have been of the order of 1-4 per annum over the past two decades. In contrast, crude estimates suggest that a minimum of 11/4 million foxes are killed annually by rabies control programmes in Europe (Zimen, E. The Red Fox, Junk, The Hague, 1980). Economic as well as conservation issues are also of relevance. A recent report commissioned by the British government suggests that the cost of badger culling to reduce the incidence of bovine tuberculosis in cattle herds far outweighs the economic benefit of control (Badgers and bovine turberculosis, HMSO, 1985).

The major problem, however, concerns the limited success achieved by wildlife culling. The extensive slaughter of foxes in countries such as France and West Germany has slowed the rate but not stopped the spread of rabies across mainland Europe. Similarly, efforts to remove social groups of badgers infected with bovine tuberculosis in areas of England and Wales have reduced the incidence of cattle-herd infection but they have not eliminated the problem. These experiences have stimulated a search for alternative or supplementary methods of

control and, in the cases of rabies, much attention has been focused on the development of safe vaccines for use in wildlife populations.

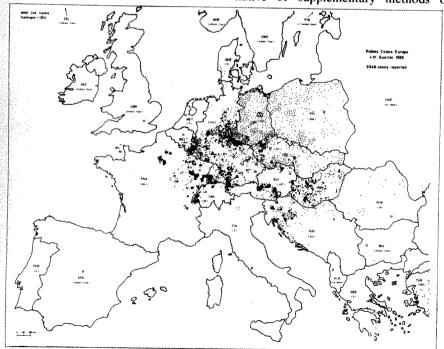

It is in this context that the work of Blancou et al. is important. Vaccines based on inactivated or attenuated rabies virus have been available for some time but their use to immunize wildlife has been restricted by poor efficacy and fears over their safety. Wildlife is vaccinated by consumption of inoculated baits (chicken heads or sausages) but this oral route of immunization for inactivated vaccines fails to induce strong protection. Oral administration of attenuated vaccines is better and appears to create effective immunity but the instability of the attenuated strains and the possibility of reversion to full virulence have prevented their use in natural habitats. Blancou and coworkers report the successful development and testing in foxes of a recombinant vaccinia virus harbouring the gene encoding the rabies surface antigen. Oral and intradermal inoculation give good protection against challenge with the wild rabies virus. The safety, efficacy and ease of administration of this new vaccine should soon lead to large-scale field trials in wild populations of foxes.

The development of a safe and effective vaccine, although essential, is only a first step in the control of infection within a population. The creation of sufficient herd immunity to block transmission is dependent on various economic and other factors, the biology and demography of the target host species and the epidemiology of the virus. A central question in the implementation of mass vaccination is what proportion of the target population must be immunized to halt disease spread. A related issue is the relationship of this critical proportion with factors such as fox density and spatial distribution.

A body of epidemiological theory is available today to help answer these questions. Simple mathematical models of the transmission of rabies in fox populations suggest that the critical proportion of animals, p, that must be effectively immunized to eradicate the infection is approximately given by

 $p > 1 - K_T/K$

Here, K_T is the critical density of foxes necessary for the endemic persistence of rabies and K is the carrying capacity of the habitat or the magnitude of fox abundance in the absence of rabies (Anderson, R.M. et al. Nature 289, 765; 1981). Epidemiological observations on rabies persistence in different habitats that support varying densities of foxes suggest that the value of K_T is approximately 0.3-0.5 foxes km⁻². The value of K is determined by the mixture of habitat types in an area and within Europe it typically lies in the range of 0.1 to 4 foxes km⁻² (Harris, S. & Rayner, J.M.V. J. anim. Ecol. 55, 575; 1986). In

some urban and suburban areas fox density may be much higher $(7-10 \text{ foxes km}^{-2})$. The equation shows clearly that the required degree of vaccine-induced herd immunity is greater in dense fox populations than in sparse ones; for K=2 foxes km⁻² the required degree of herd immunity is predicted to be approximately $80 \text{ per cent } (K_T = 0.4 \text{ km}^{-2})$. In urban areas with dense populations for example, $(K=7 \text{ km}^{-2})$ the required level of protection is predicted to be roughly 95 per cent. These figures are depressingly high and question the practical feasibility of mass vaccination as a means of control.

A further problem is created by the demography of the reservoir host species. The fox has a high fecundity (an average birth rate of 4–5 cubs per litter each year) and a short life expectancy (between 1.5–2.5 years from birth). These observations imply that a high proportion of fox populations are young animals in their first or second year of life. As such the maintainance of high levels of herd immunity would require repeated (preferably annual) cohort immunization with the aim of exposing young foxes to inoculated baits at as young an age as is practically possible.

The development of a safe wildlife vaccine as described by Blancou et al. is

clearly an important step towards the control of rabies. In practice it will undoubtedly be of value to block transmission in areas of low fox density (given that the vaccine can be produced and delivered cheaply). But in areas of high fox density, such as many urban areas in Europe (where the risk of transmission to man and his domestic animals is greatest), mass vaccination will probably have to be supplemented by culling to reduce the target level of immunization (the degree of herd immunity) required to prevent rabies persistence.

The new vaccine's greatest value may well be in the immunization of domestic animals and pets as opposed to wildlife reservoir species. In Latin America, Asia and Africa, for example, rabies in dogs presents the major threat to man (most of the estimated 15,000 annual human deaths caused by rabies occur in these regions). In densely populated urban areas, with large free-roaming dog and cat populations, baits inoculated with a safe recombinant vaccine is potentially a very attractive method of reducing the risk of

Roy M. Anderson is Professor of Parasite Ecology in the Department of Pure and Applied Biology at Imperial College, University of London, London SW7 2BB, UK.

gases, only one of which (occupying about a quarter of the volume) attracts phlogiston. This latter gas he termed Feuerluft (fire air) and eventually isolated it by heating concentrated nitric acid with charcoal, absorbing in milk of lime the red fumes of nitrogen dioxide generated. The oxygen remaining was formed by the thermal decomposition of the acid.

Scheele came close to anticipating Lavoisier by considering the possibility that during combustion fire air combines with the burning body, but he eventually concluded that the gas unites with phlogiston forming heat — which, like most of his contemporaries, he regarded as a material. This hypothesis enabled Scheele to explain why, in a few cases, a calx could be restored to a metal by heat alone, whereas normally the presence of a substance rich in phlogiston (for example, charcoal) was necessary.

Although misled by his belief in phlogiston, Scheele's record of achievement during his short life is remarkable. He discovered radiant heat, noting the similarity of its properties to those of light. His investigation of fluorite, pyrolusite and molybdenite led, respectively, to the discoveries of hydrofluoric acid, chlorine and molybdenum. He discovered glycerol and isolated a dozen previously unknown organic acids. A minor mystery surrounds his discovery of the toxic hydrocyanic acid, resulting from his investigation of the pigment Prussian blue, for he described its taste and smell.

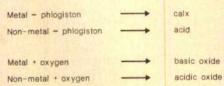

From the age of fifteen Scheele worked in various pharmacies in Sweden until, in the summer of 1775, he acquired his own pharmacy from the widow of Herman Pohl in the small town of Köping. Though subsequently offered academic posts he refused to leave his practice. A few days before his death in 1786 he married Pohl's widow and made her his heiress.

History of chemistry

Carl Scheele (1742–1786) and the discovery of oxygen

from E. L. Scott

THE birthday of oxygen is generally taken to be 1 August 1774, the day on which Joseph Priestley used a twelve-inch lens to focus the Sun's rays on the red calx of mercury (HgO), thereby liberating a gas in which "a candle burned...with a remarkably vigorous flame" (Priestley, J. in Experiments and Observations on Different Kinds of Air Vol. ii, 34; Johnson, London, 1775). But at least two years before that the Swedish chemist Carl Wilhelm Scheele, who died two hundred years ago, had already isolated oxygen. Moreover, Scheele's discovery was a confirmation of his belief in the existence of the gas, whereas Priestley's discovery was

A comparison of the phlogiston and oxygen theories of combustion. Lavoisier, like his predecessors, did not distinguish between an acidic oxide and the acid which it forms on combining with water.

totally unexpected.

transmission to man.

Scheele's experiments and conjectures are described in his only book, Chemische Abhandlung von der Luft und dem Feuer (Uppsala and Leipzig, 1777), translated into English in 1780 (Scheele, C.W. Chemical Observations and Experiments on Air and Fire (trans. Forster, J.R.) Johnson, London, 1780). Within a few years the French chemist Lavoisier named the gas oxygène, believing it to be present in all acids, and had demonstrated its role in combustion. Previously, for more than a century, burning and the calcination of metals had been explained in terms of phlogiston - a 'principle' present in all metals and inflammable non-metals. On the application of sufficient heat, the phlogiston was thought to be attracted by the surrounding air, leaving a calx in the case of a metal and an acid when the substance burned was a non-metal.

Scheele, in several experiments carried out in closed vessels observed the diminution in volume of the air and the failure of the residual air to support combustion, processes now recognizable as oxidation. He concluded that air consists of two

Ecology

Lunar cycles in lake plankton

from Geoffrey Fryer

Rнутные behaviour is an almost universal attribute of animals, the most familiar example being that of activity by day and resting by night, or vice versa. A cycle related to the movements of heavenly bodies is also shown by many intertidal animals, the lunar cycle being associated with that of the tides. These rhythms are sometimes intrinsic (or endogenous): they continue, at least for a time, when the cycle is broken experimentally. More puzzling are rhythms associated with the lunar cycle shown by certain freshwater animals, of which only a few cases are known. Some African insects with aquatic larvae emerge only at certain phases of the Moon. Maciej Gliwicz (Ecology 67, 883; 1986) now demonstrates a lunar cycle in planktonic crustaceans, a cycle that is not intrinsic but is imposed on the organisms by a predator. The study reveals a fascinating set of ecological relationships; it remains to be seen whether as yet undiscovered adaptations are involved.

In the Cahora Bassa Reservoir, Zambezi Valley, Mozambique, four cladocerans (a ctenopod and three anomopods; see figure) and two copepods (a calanoid and a cyclopoid) show changes in numerical abundance that are clearly synchronized with the lunar cycle. Such a pattern could only be revealed by frequent sampling. Monthly sampling might greatly over- or underestimate numbers, depending on the starting date, and might fail to detect the very considerable fluctuations in population size.

How can this cycle be explained? Birth rates are such that the fluctuations cannot be attributed to changes in the fecundity of these rapidly reproducing organisms. Maximum death rates, however, occur around full Moon and changes in death

Changes in population size of cladocerans in relation to the lunar cycle in Cahora Bassa Reservoir. Vertical broken lines, full Moon.

rates are clearly responsible for the fluctuations. The culprit is *Limnothrissa miodon*, a sardine-like clupeid fish native to Lake Tanganyika. Introduced to Lake Kariba, it has moved downstream and colonized Cahora Bassa. It feeds avidly on planktonic crustaceans, and calculations show that its depredations can account for even the most drastic declines observed in its planktonic prey.

There are changes in abundance of Limnothrissa adults, evidently short-lived in Cahora Bassa; annual changes in zooplankton abundance are related to these. but lunar fluctuations are not. Lunar fluctuations are caused by changes in feeding efficiency of the predator at different phases of the Moon. Limnothrissa feeds intensively throughout the night at full Moon, following the vertically migrating plankton to the surface: on moonless nights it is too dark for efficient hunting, so the predator disperses over a wide range of depths. Diaphanosoma and Ceriodaphnia begin to decline a few days before full Moon, as one might expect. In Bosmina and Daphnia, however, maximum death rates tend to occur after full Moon. Why should this be?

Gliwicz finds that stomachs of Limnothrissa are always fuller soon after full Moon than just before it, despite the similar light intensities and the fact that plankton is always more abundant before than after full Moon. Feeding intensity depends on the time of moonrise: before full Moon there is moonlight as soon as the sun sets and the plankton does not rise very near the surface; after full Moon there is complete darkness for between one and three hours, during which time the plankton ascends to the surface. When the full moon rises, its appearance is particularly

sudden in Cahora Bassa, which lies in a gorge. Plankton that has previously risen to near the surface is thus suddenly exposed to predation by Limnothrissa and is heavily cropped. Daphnia and Bosmina are apparently particularly vulnerable to this trap. This is the first time that such lunar cycles have been demonstrated, but Gliwicz thinks he can detect others in published data on planktonic Cladocera in temperate lakes cycles probably overlooked at the time as inherent sampling variations.

Since the classical work of Hrbáček (Verh. int. Ver.

Limnol. 13, 394; 1961) and of Brooks and Dodson (Science 150, 28; 1965) which shows how the introduction of a predator can alter the species composition of a plankton community, predation has been shown to have profound selective effects on the size, transparency and even on the gross morphology of planktonic anomopod cladocerans. The avoidance of predators has also long been considered to be a possible explanation of the phenomenon of vertical migration, and seems in some cases certainly to be involved. But dramatic fluctuations in abundance related to the lunar cycle suggest that planktonic crustaceans have not been able to evolve a complete response to increased predation at the time of full Moon. Avoidance of the surface waters on moonlit nights certainly reduces the effects of predation, but the trap set by the timing of sunset and moonrise is more difficult to detect and avoid.

Are such problems real or do they exist only in the human mind? Planktonic animals certainly suffer enormous mortality when caught in the Moon trap — yet they survive, and in sufficient numbers to build up their populations again within a lunar month. Fecundity may be the adaptive mechanism here: it might be advantageous to purchase grazing rights in rich pastures at the high price of periodic heavy payments.

The patterns of emergence of two African insects may be relevant to this hypothesis. In Lake Victoria the mayfly Povilla adusta emerges with a sharp peak of abundance on the second to fourth nights after full Moon (Hartland-Rowe, R. Revue zool. Bot. afr. 63, 185; 1958); in Lake Bangweulu the midge Chironomus brevibucca does so on the third to fifth nights (Fryer, G. Bull. ent. Res. 50, 1; 1959). Such synchronized emergence has the obvious advantage of facilitating the finding of mates. Swarming and spawning of marine organisms, essentially polychaetes, with similar lunar rhythms takes place at similar Moon ages. P. Korringa (Mem. geol. Soc. Am. 67, 917; 1957) has shown how marine animals might use moonlight to time and to synchronize their maturation, and this explanation fits the observed emergence times of P. adusta and C. brevibucca. In both species emergence takes place very near the phase of the Moon when the insects are most vulnerable to predation, and both are eaten extensively. Again, however, these species may find it advantageous to pay this price to achieve synchronized emergence at a convenient phase of the Moon. In the case of C. brevibucca, the numbers emerging are so immense that even heavy predation is trivial.

Cognitive neurophysiology

Signs of language in the brain

from John C. Marshall

THOSE of us with intact hearing are often inclined to dismiss the manual communication of deaf people, discussed in a study reported on page 363 of this issue', as a mishmash of pantomime and iconic signals, eked out by finger spelling. In many teaching institutions committed to strict 'oralism', signing was (and in some instances still is) firmly suppressed, with disastrous consequences for the deaf child's educational attainment2; even in academic discussion, sign language was frequently

regarded as, at best, a primitive pidgin, and not a 'real' language.

Yet in Europe, true sign languages, with all the formal complexity and expressive power of spoken language, are known to exist in (at least) Austria, Denmark, Finland, France, Germany, Norway, Portugal, Rumania, Sweden, Switzerland, the Soviet Union, the United Kingdom and Yugoslavia. These different, often mutually unintelligible languages, which have little or no superficial similarity with the local spoken languages, have been passed down through the generations from deaf parents to their deaf (and often hearing) children.

American Sign Language (ASL) branched off from

French Sign Language some two hundred years ago, and the current intense interest in the linguistic structure of ASL derives in large measure from the pioneering work recently undertaken by Ursula Bellugi and Edward Klima' at the Salk Institute in California. Once the formal structure of manual signing had been elucidated - how hand configuration,

position and movement through space (including change in hand configuration) combine to express vocabulary and syntax - it was clear that ASL is indeed a fullyfledged language that can serve every day conversation, intellectual argumentation, wit and poetry4. But now there arises an interesting issue about the neuronal substrate for sign.

The basic complementary organization of the duplex human brain is between speech processing (committed to the left

Movement trajectories of grammatical processes (courtesy of U. Bellugi).

cerebral hemisphere) and visuo-spatial together with visuo-manipulative processing (committed in the main to the right hemisphere). A central question in the psychobiology of language is thus whether the underlying specialization of the left hemisphere is restricted to auditory-vocal language (that is, speech), or rather includes a more 'abstract' representation of linguistic form (grammar), irrespective of the mode in which it is expressed

Natural sign languages provide a privileged insight into this question. Such a system simultaneously qualifies as a language and as an extremely complex and precise set of gestures, executed in space and perceived visually. Nonetheless, studies of disorders in the expression and comprehension of sign consequent upon unilateral brain damage show that, just as with aphasia for spoken language, it is left hemisphere damage that provokes these sign language aphasias67; by contrast, in deaf patients with extensive right hemi-

sphere damage, signing is little disturbed. although many non-language visuo-spatial tasks (including drawing) may show severe impairment 8.9. It would seem, then, that it is language per se (not solely speech perception and production) that is lateralized to the left cerebral hemisphere. Grammatical structure is processed by the left hemisphere even when the overt physical realization of that structure involves a visuo-spatial medium.

The case now reported by Damasio, Bellugi, Damasio, Poizner and Van Gilder demonstrates in even stronger fashion that the above conclusion is warranted. Their patient, a young woman with normal hearing, spoke English but was also proficient in ASL as a second language; she earns her living as an inter-

> preter and counsellor for deaf people whose native language is ASL. Unfortunately, she suffered increasingly from frequent partial complex seizures that could not be controlled pharmacologically. gical intervention - resection of the temporal lobe was therefore considered. But which temporal lobe (left or right) should be ablated? Bilateral temporal lobectomy results in a gross amnestic syndrome that precludes any kind of normal life; removal of the language-dominant temporal lobe could result in aphasic impairment that would destroy the patient's livelihood.

The application advanced in vivo brain imaging techniques showed anatomic and metabolic

asymmetries consistent with normal left hemisphere processing of speech in the patient. More direct evidence for the control of language skills was then obtained by barbiturate injection. The brief inactivation of frontal and central areas of one hemisphere (which include languagecommitted cortex) can be achieved by injection of sodium amytal into the ipsilateral carotid artery. When this was performed, a reversible lesion (pharmacologically induced) of the left hemisphere produced in the patient a temporary aphasia for English and ASL; left cerebral dominance for both language systems was thereby indicated, and the severity and the duration of the sign language impairment was even greater than in spoken English. Subsequent neurosurgical intervention - partial resection of the right temporal lobe - was found, three and twelve months post-operatively, to have produced no neuropsychological impairment of either English or sign language.

The patient continued to manipulate the spatial syntax of ASL with the same fluency she had shown pre-operatively. Dr A. Damasio reports (personal communication) that the patient has been seizure-free since the operation and has successfully returned to her demanding work as a sign-language interpreter.

These results, then, provide further testimony for the modular organization of the human brain; different domain-specific cognitive representations are computed by the two halves of the adult brain, irrespective of the physical form whereby

those representations are made manifest. It is, however, possible that by virtue of their combined linguistic and visuospatial nature, the facile acquisition of signs requires both hemispheres to be fully intact. Damasio, Bellugi and their colleagues now intend to investigate how easily their patient can learn new signs, including the quite distinct space structures of Chinese Sign Language.

Solid-state physics

New semiconducting polymers

from R.H. Friend

THE discovery in 1977¹ that the addition of small amounts of strong oxidizing or reducing chemicals to polyacetylene (doping) produces levels of conductivity typical of metals contradicted long-held views that electrons in organic semiconductors necessarily have low mobilities. Progress since then has been impeded by the limited availability of polymers with desirable properties and also by difficulties in processing them. This constraint has been loosened by S.A. Jenekhe, who on page 345 of this issue² reports the smallest energy gap yet obtained in an organic polymer, which brings closer the

use of this class of compounds as semiconductors and transparent conductors.

The feature common to the organic semiconductor class of polymers is the presence of pon each atom on the chain, giving a conjugated structure which can be represented (slightly misleadingly) by alternation of 'double' and 'single' bonds. Overlap of adjacent p, orbitals gives welldelocalized π electron wavefunctions and high electronic mobilities. These polymers do not conform to the models that work for inorganic semiconductors.

Whereas it is can be said that threedimensionally bonded inorganic semiconductors are semiconductors by accident (that is, there happens to be an energy gap between the highest occupied and lowest unoccupied levels), the same is not true for 'one-dimensional' polymeric semiconductors, where it is energetically favourable to set up the interatomic spacings along the chain so that there is an energy gap between the highest π and the lowest π^* levels.

The semiconductor gap in the *trans*-isomer of polyacetylene is caused by alternation of bond lengths along the chain;

this dimerization introduces an energy gap between the occupied π 'bonding' states (which have high electron density in the short, double bonds) and the unoccupied π^* states (with electron density in the long, single bonds). The strength of the bond alternation, and hence the size of the energy gap, is determined by the trade-off between the cost in elastic strain energy associated with the distortion and the reduction in π electron energy that it achieves. The observed gap is approximately $1.5 \, \mathrm{eV}$.

The particular novelty in trans-polyacetylene is that the sense of bond alter-

Bond-alternation defect (shown as the neutral defect) separating the degenerate A and B phases of trans-polyacetylene (above); and a positively charged bipolaron defect on a poly(phenylene) chain, showing the quinonoid character within the defect (B phase) and benzenoid character (A phase) elsewhere on the chain (below).

nation is not determined, so that there are two, degenerate phases, labelled A and B in the figure. In consequence the chain can support stable defects in the bond alternation sequence, separating the A and B phases as shown in the figure. These topological defects, which have an associated 'non-bonding' p, level, are calculated to move along the chains as low-mass particles and possess most of the qualities of solitary waves (solitons). Furthermore, the result of adding charge to the chain, through chemical doping or following photoexcitation, is always to create these defects, which can be positively charged

(p_z level empty, spin 0), neutral (one electron on p_z level, spin $\frac{1}{2}$) or negatively charged (p_z level doubly occupied, spin 0). This is in contrast to the doping of traditional, inorganic semiconductors in which added charges are present as holes in the valence band or electrons in the conduction band.

For most of the other conjugated polymers that have been synthesized, the sense of bond alternation along the chain is determined, and the A and B phases are non-degenerate. For the polyphenylene chain illustrated in the figure, the benzenoid (A) phase is lower in energy than the quinonoid (B) phase. The usual consequence of this is that there is now an additional contribution to the semiconductor gap (π levels are of benzenoid character, π^* levels quinonoid), and indeed this is true in many cases, including polyphenylene (3 eV) and polythiophene (2 eV). Soliton defects are no longer stable, although in pairs they can form 'polaron' defects with a short length of B phase on the chain. Although the polaron defect is not stable on a neutral chain, it does provide the cheapest way of accommodating charges added to the chain, either as a singly charged polaron or as a doubly charged bipolaron (see figure).

Hence the discovery of conjugated polymers with band gaps smaller than that of polyacetylene was unexpected. To obtain these small band gaps it is necessary to design the polymer so that the energy difference between the A and B phases is as

small as possible, and this is apparently achieved in polyisothionaphthene' which has a gap of slightly more than 1 eV. An alternative strategy is to design a polymer which is forced to have alternating sequences of the A and B phases along the chain so that there is little difference in the benzenoid/quinonoid character in the π and π^* states. Jenekhe has achieved this for a class of thiophene-derived polymers that reduce the gap to as low as $0.75 \, \mathrm{eV}$.

Narrow-gap conjugated polymers will extend the scope both for applications and for fundamental investigations. Much as for

inorganic semi-conductors, narrow-gap materials should show high electronic mobilities. In the context of the polymers, the soliton and polaron defect states will be delocalized and have low effective masses. This is desirable for many semi-conductor applications and, in addition, these materials can be transparent in the visible part of the spectrum and are thus of use as transparent conductors.

Beside the tuning of electronic properties that is now achieved with new synthetic routes, processibility via a soluble phase, either a 'precursor' polymer or a conjugated polymer with soluble side

groups', is now routine. Well-crystallized and highly oriented films of several precursor-route polymers can obtained by stretch orientation during transformation; these films have allowed the first experimental investigations of the anisotropy of electron motion along or between chains78. Although electron motion along chains is easy, it is important to recognize that the degree of contact between the π electron wavefunctions on adjacent chains is quite strong, and that interchain electron motion is not difficult. Experiments using oriented polyacetylenes demonstrate that the quantum yield for photogeneration of charged pairs is higher when the band-gap illumination is polarized perpendicular, rather than parallel, to the

chains, so that the photons absorbed transfer electrons between chains. The scope for development of the highly dichroic properties of these materials is vast.

Meteorites

Window on the early Solar System

from Derek Sears

It is an oft-repeated truism that meteorites are a window on the early Solar System. They are, however, complex: the astronomer B. Pagel once remarked, after taking a cursory glance through the window, that "the oracle is . . . wrapped in obscurity of truly Delphic proportions". Fortunately, Pagel was unduly pessimistic, because the window sometimes clears to present a unique and fascinating picture of places and processes as they were 4,600 million years ago, as shown in a recent paper by David Wark2.

One of the most important developments in the study of meteorites over the past few decades is the realization that some meteorites retain a better record of the nebular phase of their history than others; these primitive or type 3 chondrites contain many individual components with particular significance for deciphering the earliest history of solid matter in the Solar System. Some of the better-studied components are the silicate aggregates called chondrules3; the finegrained, almost smoke-like, matrix4; certain kinds of metal grains; and the graphite-magnetite aggregates6. But the objects which have attracted the most attention are calcium-aluminium-rich inclusions (CAIs), one of which is the subject of Wark's paper.

Wark describes a CAI discovered in the Allende meteorite shortly after it fell in 1969. The inclusion (CAI 3643) consists of a core, mantle and crust. The crust appears to have been formed by rapid episodic condensation and aggregation in a compositionally unchanging gas. The core consists predominantly of hibonite, a mineral which is one of the first to condense in a gas of solar composition, whereas the mantle and crust consist predominantly of melilite, which is thought to form by re-

action between the hibonite and the gas. The core has the texture of a material which formed by deposition from a vapour. There are many metal nuggets in the centre of the core which consist of highly refractory trace elements, whereas those in the outer parts of the core contain elements of less refractory nature - it is as if they mopped up the elements missing from the nuggets at the core's centre. Other refractory trace elements, the rareearth elements, show a steady decrease in abundance with increasing volatility, as if the formation of the CAI occurred over the same temperature interval as the elements were condensing.

All these details are consistent with an episodic condensation and accretion of the core, with the mantle and crust being made by later episodes of condensation onto the earlier-formed solids. The processes occurred at high temperatures and involve solids which are refractory to various degrees. Once formed, the entire assemblage suffered several alteration processes at much lower temperatures. with evidence for metamorphism, metasomatism and the introduction of a vapour rich in halogens, alkali metals and iron.

Many who have worked on this CAI have suggested that the inclusions, or some material in them, were not formed in our Solar System, but were transported here from interstellar space during or just before the formation of the Solar System. This idea is rooted in the unusual isotope ratios frequently encountered in the inclusions. It was long believed that the isotopes in our Solar System became thoroughly mixed during its formation. CAIs also contained several short-lived radioactive isotopes at the time they were formed. Some of the nuclides have very short half-lives (for example *Al, 0.72

million years), which has suggested that the event which ejected the isotopes into the interstellar medium (say, a supernova explosion) was that which triggered the formation of the Solar System. Thus, the condensation sequences would have occurred in the expanding and cooling shells of ejected supernova materials

An alternative view is that interstellar material, with essentially normal chondritic composition, entered the primordial solar nebula at cosmic velocities and became heated in a manner analogous to meteorites entering the atmosphere ". The evaporation sequence as the material is heated would be the reverse of the condensation sequence, so that CAIs can be regarded as distillation residues rather than high-temperature condensates

Wark points out that the properties of CAI 3643 are not consistent with ideas that involve exposure to various chemical environments. Although the zones in the inclusion, and the radial gradients in mineralogy and refractory-element chemistry, imply different temperature regimes for the aggregation processes, they must have occurred quickly for the differences to have persisted, and they must have occurred in a gas which did not change very much in its composition. Instead, Wark suggests that the CAI formed in a single place and over a fairly restricted time interval; he favours the formation of the CAI by episodic condensation and aggregation during localized transient heating events in the asteroid belt.

Wark's paper will not lay to rest the idea that CAIs are extra-Solar System in origin. It is always possible, although unlikely, that the various extra-Solar System atmospheres that have been postulated were compositionally very similar and movement from one to another was very rapid. It is also possible that not all CAIs were created in the same way. But Wark provides a clear indication that, in at least this instance, the condensation and accretion sequence was followed episodically and in a very restricted regime of time and environment. In this sense, our window on the early Solar System has cleared a little, and provided us with a view that can be obtained in no other way.

Geometry

Exotic structures on four-space

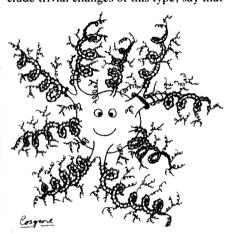

from Ian Stewart

ONE of the biggest surprises in topology was the discovery in 1982 that fourdimensional euclidean space does not have a unique structure as a differentiable manifold. The existence of an 'exotic' structure on four-space was proved by Michael Freedman, by combining his techniques for analysing four-manifolds (J. diff. Geom. 17, 357; 1982) with a new and startling result due to Simon Donaldson (J. diff. Geom. 18, 279; 1983). A question that immediately arose was how to classify all such structures: in particular, how many are there? Robert Gompf (J. diff. Geom. 18, 317; 1983) found four distinct differentiable structures - the standard one plus three exotics. A fifth universal' structure (containing all the others) was found by Freedman and Larry Taylor. And now Gompf has shown (J. diff. Geom. 21, 283; 1985) that there exists an uncountable infinity of exotic structures on four-space.

A differentiable manifold is a multidimensional analogue of a smooth twodimensional surface. The idea is of central importance in mathematics and has applications throughout the physical sciences. For example, the motion of the Moon, the Earth and the Sun under their mutual gravitational influence corresponds to the motion of a point on an 18dimensional 'phase space' having three dimensions of position and three of momentum for each body. The original idea goes back to Bernhard Riemann in 1854; in its modern form it is due to Hermann Weyl in the 1930s. An ndimensional manifold is a collection of overlapping 'patches', each looking like a piece of *n*-dimensional euclidean space. Each patch inherits a coordinate system, which means than on each overlap there are two distinct coordinate systems - one from each patch. These do not necessarily agree; but if each is related to the other by a differentiable transformation, then the system of patches is said to define a differentiable structure on the manifold.

For example consider an ordinary twodimensional sphere. This can be considered as two overlapping patches, each forming rather more than a hemisphere. For example, in geographical terms, let one patch be everything south of the Tropic of Cancer, and let the other be everything north of the Tropic of Capricorn. The overlap is an equatorial band between the two tropics. Each patch is a distorted circular disk, and it is not hard to find coordinate systems on the disks that provide smooth overlaps. An *n*-dimensional hypersphere can be defined by an analogous construction, using two balls in *n*-dimensional space.

It is easy to see that a given manifold can have many different differentiable structures, that is, systems of smoothly overlapping patches. But the obvious examples are related in an essentially trivial way. Start with a manifold M and a differentiable structure S. Take any continuous one-to-one correspondence of M with itself and apply it to all of the patches describing S, to get a new set of patches S'. Then, in general, S' is different from S, but the patches of S' fit together to give the same manifold as those of S. To exclude trivial changes of this type, say that

Artist's impression of an exotic four-space. The structure resembles ordinary four-space at the centre, but becomes more and more complicated as it approaches infinity, putting out branched tentacles in all directions. This conjectural picture compresses four dimensions into two, and is correct, if at all, only in spirit. An explicit description of the true geometry is not yet known.

under these circumstances S and S' are 'equivalent'. Then a more interesting question arises: can there be several inequivalent differentiable structures on the same manifold?

Early results suggested not: for example, it was proved in the 1950s that if the manifold is three-dimensional then there is a unique differentiable structure up to equivalence. However, matters took an unexpected turn in 1963 when John Milnor proved that the seven-dimensional hypersphere has at least two inequivalent differentiable structures: the 'standard' one and another exotic one. A detailed study of these exotic spheres revealed that there are exactly 28 inequivalent differentiable structures on the 7-sphere.

Even so, it was not expected that this kind of trouble would show up in ordinary euclidean *n*-space. Indeed it was known

that for $n \neq 4$ there is a unique differentiable structure. The conjecture that uniqueness holds for all euclidean spaces lay at the heart of smoothing theory, a method for studying non-differentiable manifolds by providing them with a differentiable structure. So it was quite a shock when Freedman and Donaldson showed that four-dimensional space behaves in a completely different and rather horrifying way. There exist 'exotic R's', that is, differentiable structures on four-space that are not equivalent to the standard one (see figure).

The problem is to tame these unruly structures by imposing some comprehensible order on them. Which brings us back to the question: how many exotic R's are there? Mathematicians distinguish many different 'sizes' of infinity. The cardinal of a set is the size of infinity that corresponds to it. The smallest cardinal, called aleph-zero, or countable infinity, is that corresponding to the set $\{1,2,3,\ldots\}$ of positive integers. A set is countably infinite if it can be put into one-to-one correspondence with the positive integers. Many sets — pairs of integers, the rational numbers, the algebraic numbers — are countably infinite. But the set of real numbers cannot be put in one-to-one correspondence with the positive integers, and is said to be uncountably infinite. There is a consistent arithmetic of infinite cardinals; it has its own bizarre logic, and there are many pitfalls. For example, it is possible for one set to contain another (and thus be 'bigger') even though both sets have the same cardinal.

Gompf first found a family R, of exotic R^4s , where s and t are positive integers, with the property that R, embeds in R, if and only if $s \le u$ and $t \le v$. In particular R_{ij} is equivalent to R_{us} only when s = u and t= v. This provides a countably infinite set of inequivalent exotic R4s. Clifford Taubes has now developed a generalization of Donaldson's results, inspired by an observation of Freedman that such a generalization would imply the existence of an uncountable infinity of exotic R's. This idea can be applied to Gompf's construction, and it yields an even more extensive family of exotic R's. It is probable - but not yet certain - that these results give the correct cardinal for the set of all exotic R's. That does not mean that Gompf's examples exhaust all possibilities, because 'larger' sets can have the same cardinal. Indeed Taubes's set is smaller than Gompf's, yet the cardinal is the same in both cases.

The set of all exotic R's also carries a natural algebraic operation, the 'end-sum'. There are a number of analogous operations in topology. The simplest combines two knots to yield their 'sum' by tying both in the same piece of string. Similarly the connected sum of two manifolds can be obtained by cutting a small

disk out of each and gluing a tube between the holes that result. (Milnor showed that such a construction applied to his 28 exotic 7-spheres turns them into a very nice algebraic object: a group.) The end-sum of two exotic R's is obtained by 'gluing them together at infinity'. To find an abstract description of the structure of the set of all exotic R's under the end-sum operation is a problem of central importance. It would not only classify them all, but also explain how they relate to each other.

The importance of these ideas for mathematics is manifest. We know that four-dimensional space differs in a dramatic and rich way from all other dimensions. It is obviously of fundamental interest to explore exactly how and why this occurs.

The relevance to applied science is not

so clear: the 'standard' structure on fourspace is after all the one suggested by physical observation. But the influence of mathematics and applications on each other, while profound, is seldom immediate and hardly ever direct. For example the existence of exotic R's is established by combining some recent ideas in quantum physics — gauge field theories — with some extremely abstract techniques of modern topology. The same combination is appearing in basic questions about unifying the forces of nature. A fundamental mathematical truth is important because, once proved true, it stays true. Exotic R's are abroad in the world, and the world is changed - forever.

Computational cosmology

Galactic haloes need computers

from George Efstathiou

OBSERVATIONS of rotation in spiral galaxies suggest the presence of dark material in haloes surrounding the luminous component. Little is known about the nature of this dark matter — it could be black holes, ultra-small 'stars' or even elementary particles such as massive neutrinos, photinos or gravitinos. However, the way that the rotation speed varies with distance from the centre of a spiral suggests that the mass in the halo increases linearly with radius. This behaviour is important for at least two reasons. The first concerns the origin of the observed spatial distribution and whether it arises naturally from small perturbations which grow by the action of gravity. The second concerns the total extent of the dark haloes, and whether there is enough dark matter so that the Universe will eventually collapse back to a singularity. The first of these questions is addressed by P.J. Quinn, J.K. Salmon and W.H. Zurek elsewhere in this issue (Nature 322, 329; 1986) and both questions were among those discussed at a recent meeting*.

Quinn et al. use computer simulations which model the gravitational interactions between a large number of mass points to study the formation of structure in an expanding universe under various assumptions concerning the initial conditions. If the mass points are initially distributed at random (white noise), then the haloes that form in the simulations are more centrally concentrated than indicated by the observations. But the authors also show that density fluctuations with significant contributions from long-wavelength perturbations (more like 'pink noise'), develop

haloes with a linear mass distribution resembling that around spirals.

Interestingly, the pink-noise irregularities arise naturally if the dark matter is in the form of weakly interacting massive particles such as gravitinos. The evolution of structure in such models has been investigated using computer simulations by C.S. Frenk et al. (Nature 317, 595; 1985) who showed that the model broadly accounts for the distribution of mass in haloes

and their abundance in space.

But what relation do these studies have to the models of galactic distribution and clustering that follow from cosmic string theories? There are very significant differences: the underlying assumption of the gravitating mass-point studies is that statistics of the initial fluctuations are gaussian, whereas strings introduce considerable skewness — which may lead to clustering and superclustering; furthermore numerical models of the strings developed so far exclude gravitational forces. The two types of study clearly need to be combined in a single model, but the computer code to do the job has not yet been written — largely because of the power and time that are necessary to handle simultaneously gravitating mass points, strings and internal string forces.

Why do we need computer simulations at all in such problems? The answer lies in the non-linear nature of gravitation. In general, it is not possible to study the evolution of a gravitating system of mass points by analytic methods unless one adopts highly restrictive assumptions such as spherical symmetry. Furthermore, in the cosmological context described above, halos do not evolve as isolated systems. Rather they form through a complicated

series of mergers between smaller subunits. It seems unlikely that we will readily develop an analytic theory capable of reliably modelling such events. Yet can we believe computer simulations which typically contain less than 50,000 mass points. some six orders of magnitude less than the number of stars in one galaxy? Does the artificial 'graininess' or the presence of boundaries in computer simulations adversely affect the results? The answer is ves in some cases and no in others, and it is up to the numerical experimenter to convince his readers of the reliability of key conclusions by applying appropriate tests. Sadly, this has not always been done in the past and many researchers, in other fields as well as in cosmology, remain sceptical of the computer simulations.

There are also other issues. In the present mass-point studies, essentially any 'clump' that forms is considered to be a galactic halo. The familiar flattening of galaxies into disks does not occur because it requires dissipating forces, such as radiative cooling from high-density gas. Consideration of these effects requires a hybrid program that can handle both gas dynamics and gravitational mass-point interaction. Since a full model must also take into account feedback effects where star formation can raise intergalactic gas temperatures from microwave background levels to 10,000 K, the ultimate computer model of galaxy formation is bound to be highly complex.

Much larger simulations could be achieved by using improved algorithms, a new generation of supercomputers, or both, as discussed at the meeting. Most present-day computers are simple uniprocessor machines: the current generation of supercomputers such as the Cray-XMP or Cyber-205 achieve a high performance by applying the same instruction simultaneously to many pieces of data which belong to a 'vector'. The US National Science Foundation has set up several centres for large-scale scientific computing where the computers will be coarse-grained parallel machines such as the ETA-10. This enormous computer consists of &

100 years ago **Animal Intelligence**

A REMARKABLE instance of animal intelligence has lately come under my notice. In a neighbour's bungalow in this district two of our common house-swallows (Hirundo javanica) built their nest on top of a lamp that hangs in the dining-room. As the lamp is either raised or depressed by chains fixed to a central counterweight, these chains pass over pulleys fixed to a metal disk above, on which the nest was placed. The swallows built over each pulley a little dome, allowing sufficient space, both for wheel and chain to pass in the hollow so constructed. without danger to the nest, which was not only fully constructed, but the young birds were reared without further danger

From Nature 34, 265; 22 July 1886

^{*}Use of computers in stellar dynamics, 2-4 June 1986, Institute for Advanced Study, Princeton, New Jersey, USA.

Cyber-205 machines with a massive shared memory. At the other end of the spectrum, fine-grained parallel machines such as the Connection Machine use many simple processors which communicate with each other via a complicated network of interconnections.

The optimal algorithm for solving the gravitational n-body problem clearly depends on the architecture of the machine. Existing programs such as Aarseth's famous n-body code can easily be adapted for vector machines and will be used extensively at the supercomputer centres. Algorithms for very fine-grained computers (which use many simple processors) are likely to be quite different. Several ingenious possibilities were described at the meeting (Joshua Barnes, Institute for Advanced Study, Princeton).

Very few cosmologists and astrophysicists have thought seriously about building their own special-purpose supercomputer, yet it is feasible to acquire the

necessary skills (Gerald Sussman, MIT). Sussman also argued that it is now possible to build one-off machines to study the stellar dynamical evolution of, say, an entire globular star cluster containing one million stars.

But even the globular cluster problem is not entirely stellar dynamical. At some point during evolution, the finite sizes of stars may become important, as may mass-loss and other astrophysical effects. In the case of cosmological simulations, our lack of knowledge of gas dynamics and star formation impose severe limitations on our understanding. Supercomputers will undoubtedly make a major impact in cosmology and astrophysics, but in many cases they will solve only idealized problems. Theorists will still have plenty to do in applying the results to real stellar systems.

Nitrogen fixation

A role for vanadium at last

from R. Cammack

FIFTY years after Bortels reported that vanadium could substitute for molybdenum as a trace element essential for nitrogen fixation in the soil bacterium Azotobacter vinelandii, Robson et al., on page 388 of this issue², report conclusive evidence for an alternative vanadiumcontaining nitrogenase from A. chroococcum, a result made possible by recent developments in the genetics of nitrogenfixing bacteria. Robson et al. produced a mutant strain in which the structural genes for the normal molybdenum-containing nitrogenase are deleted and demonstrate that the alternative nitrogenase uniquely requires vanadium for its synthesis, and in stoichiometric amounts.

The complex, nitrogen-fixing enzyme nitrogenase has two types of protein component, both containing iron-sulphur clusters. One of these components, the iron-molybdenum protein, also contains a cluster of unknown structure, the iron-molybdenum cofactor (Fe-Mo-Co): there is compelling evidence that this is the site at which dinitrogen is reduced to ammonia. The function of the other component is to 'pump' electrons, using energy from ATP, into the iron-molybdenum protein. The vanadium-containing nitrogenase appears to have a very similar arrangement, a structure containing vanadium presumably substituting for the Fe-Mo-Co, although the proteins involved are the products of different genes.

Chemically, the substitution of vanadium for molybdenum makes good sense. The two elements are capable of | its presence was not detected. A recent |

similar oxidation-reduction reactions at low redox potentials. Model compounds for the nitrogenase reaction that can catalyse the reduction of dinitrogen to ammonia have been synthesized, most containing molybdenum, although complexes of vanadium are also effective3.

Ironically, although nitrogenase was partially purified from vanadium-grown A. vinelandii about 15 years ago and several of its catalytic properties, such as decreased sensitivity to cobalt inhibition, correctly described, the significance of vanadium in this system was not recognized. This was partly because of the extreme difficulty of obtaining growth media that were sufficiently molybdenum-free, which meant that all nitrogenase preparations contained a certain amount of molybdenum. It must have seemed unreasonable at the time to assume that there existed a second nitrogenase system with almost identical protein structure to the molybdenum nitrogenase system, which rapidly decomposes during purification and has very little activity in the conventional acetylene-reduction assay. Instead it was concluded that vanadium had a 'sparing' effect, stabilizing the molybdenum nitrogenase when molybdenum was in short supply. The idea that all nitrogenases contain molybdenum became firmly established and molybdenum was routinely added to all growth media for nitrogen-fixing organisms. Because the synthesis of the vanadium nitrogenase is repressed even by traces of molybdenum, survey of the literature showed that Bortels' 1930 paper describing a requirement for molybdenum in nitrogen fixation has been cited 55 times, while his 1936 paper describing the alternative use of vanadium was cited 4 times.

The more recent discoveries stem from the work of Bishop⁵ who, in the face of much initial scepticism, demonstrated the presence of a second nitrogenase system in A. vinelandii grown in molybdenumdeficient conditions. He obtained a nif mutant which could not express the conventional molybdenum nitrogenase, but which could still grow by fixing nitrogen in the absence of molybdenum. He showed that these 'pseudo-revertants' were tungstate resistant and expressed a different nitrogenase whose activity (as measured by hydrogen production) was less sensitive to inhibition by acetylene, carbon monoxide or tungstate. It appears that it was the vanadium present as a contaminant in tungstate that allowed Robson et al.2 to discover the vanadium enzyme.

Azotobacter synthesizes the molybdenum nitrogenase in preference to the vanadium nitrogenase when molybdenum is available presumably because the molybdenum enzyme is more stable, and possibly catalyses less of the wasteful side-reaction in which hydrogen is produced. Although molybdenum is difficult to remove from laboratory media, it may become a limiting factor in some soils, and hence the capacity to make the alternative nitrogenase confers a selective advantage. A question of great interest is whether other nitrogen-fixing organisms, and in particular the economically important rhizobia, are capable of making the vanadium nitrogenase.

Macara⁶ has described vanadium as "an element in search of a [biochemical] role". It is known that vanadium in extremely small amounts is a nutritional requirement for many types of organism, possibly including higher animals'. The sea-squirt Ascidia nigra contains high concentrations of V(III) ions in specialized blood cells. Vanadium is also accumulated by the toadstool Amanita muscaria8 and a vanadium-containing bromoperoxidase has recently been isolated from a seaweed, Ascophyllum nodosum9. With the establishment of vanadium in nitrogenase, its role is beginning to emerge.

SCIENTIFIC CORRESPONDENCE

Observation of ^{110m}Ag in Chernobyl fallout

Sir—The initial radiometric flurry of interest in fission products with relatively short half lives following the Chernobyl reactor accident has been replaced with concern about the entry of fission products with longer half-lives into the food chain.

The movement and slaughter of lambs in Wales, Cumbria and Scotland has recently been prohibited due to the identification of lamb meat containing abnormally high levels of 134 Cs (T_{12} =2 yr) and 137 Cs (T_{12} =30 yr).

The radiometric laboratory of the Department of Physics at the University of Liverpool, which houses several low-level γ-ray counting systems, has been employed to carry out measurments on various dairy and meat products originating from North Wales. The low-level counting systems consist of high-efficiency, hyperpure germanium detectors with Compton suppression shields enclosed in lead castles to reduce background radiation. All systems are efficiency calibrated so that radionuclide concentrations can be determined.

A recent study of beef and lamb products in this laboratory revealed the presence of the radionuclide 110m Ag ($T_{1/2}$ =250 days) in both beef and lamb liver but not in other meats from the same animals. This radionuclide is readily identified by the presence of a γ -ray line of 658 keV alongside the characteristic 662 keV line of 137 Cs, although several other γ -rays including those at 447, 620, 707, 764, 885 and 937

keV provide an unambiguous identification of 100s Ag.

A relevant portion of the γ-ray spectrum shown in Fig. 1 indicates the excellence of the detection system with its low background contribution and the clear resolution of the 658 and 662 keV lines.

Although the levels of Hum Ag are small in both the beef and lamb liver, this radio-nuclide has not been observed in any other samples measured in this laboratory including air filters, rainwater and milk measured on 5–9 May 1986, nor in other meats and from ecological studies since.

In the beef liver we observed 23 ± 1 Bq kg⁻¹ of ^{110m} Ag, 19 ± 1 Bq kg⁻¹ of ¹³⁴Cs and 21 ± 1 Bq kg⁻¹ of ¹³⁷Cs. In lamb liver we observed 74 ± 1 Bq kg⁻¹ of ^{110m}Ag, 30 ± 1 Bq kg⁻¹ of ¹³⁴Cs and 48 ± 1 Bq kg⁻¹ of ¹³⁷Cs.

The radionuclide ^{110m}Ag is unlikely to arise as a fission product of ²³⁵U. A=110 is near the minimum of the saddle point in the asymmetric mass distribution arising from the fission of ²³⁵U by thermal neutrons. Also, a neutron-rich mass chain of A=110 produced in fission would terminate after successive β -decays at the stable nucleus ¹¹⁰ Pd before ^{110m}Ag could be reached.

A more plausible explanation is that the ^{110m}Ag is generated via the ¹¹⁰ Cd (n,p) ¹¹⁰Ag reaction. Cadmium has been widely used in nuclear reactors as a neutron absorber for control purposes, however, following the Chernobyl reactor accident, cadmium may well have been used to try to control self-sustaining fission after the core meltdown.

As liver acts as a filter for large particles in the blood it is perhaps surprising that

Further study of the lungs, liver and kidneys of animals reared in the areas of heavy fallout may provide yet more information concerning the Chernobyl accident.

G. D. Jones

P. D. FORSYTH P. G. APPLEBY

Oliver Lodge Laboratory, University of Liverpool, Liverpool L69 3BX, UK

Sir-Fission product radioactivity from the Chernobyl reactor accident was first detected in air samples at Oak Ridge. Tennesee on 10 May 1986. The aerodynamic sizes of the aerosol-associated fission products were evaluated in four measurements made during the period 7 May to 13 June, using Sierra high-volume cascade impactors and low-background intrinsic germanium coaxial and well detectors. Additional air and precipitation samples were also obtained over this period. The Chernobyl activity was mostly sub-micrometre in size, and the particle size increased significantly over the measurement period. Only a small fraction of the aerosol "I was soluble in CHC1,. Both 134,137 Cs and 183 Ru were less soluble than natural radioactivity, indicating some association with aerosols produced by the accident.

Two distinct phases in airborne radioactivity were evident in our measurements. The first phase lasted from 10 to 17 May and was characterized by a "Cs/" Ru activity ratio of ~1.5, resembling the airborne fission products and deposition. reported in Finland on the 28-29 April The second phase began on 18 May, when precipitation from a convective storm yielded much higher "Ru and "Ba activities, relative to "Cs, than previously found in air or precipitation. This resulted in 137 Cs/ 102 Ru ratios of <0.8, similar to that calculated from British data³. Subsequent air and precipitation samples showed that this lower 137Cs/103Ru ratio persisted until 13 June. Table 1 summarizes these

The change in ¹⁰Cs/¹⁰⁰Ru ratio on 18 May is interpreted as reflecting separate releases from the reactor which were meteorologically and/or temporally isolated. Two separate maxima in radioactivity were reported in Sweden, one on 28 April and one in the first week of May. The highest measured air concentration of ¹⁰⁰Ru, 3.7 mBq m⁻³, occurred in the 20–23 May sample By 3 June, ¹⁰¹Ru had declined to 0.1 mBq m⁻³. We have also measured the amount of aerosol ¹³¹I and its chemical

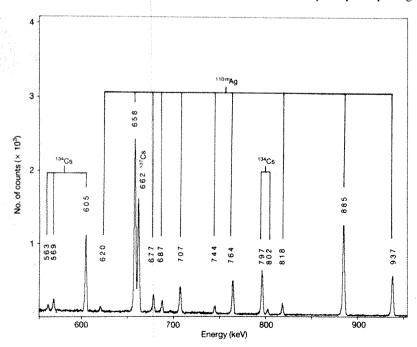

Fig. 1 A partial γ-ray spectrum arising from a sample of liver from a Welsh lamb. The count time was 57,700s. The lines are labelled by their energies in keV and by the originating radionuclides ^{110m}Ag, ¹³⁴Cs and ¹³⁷Cs.

composition. One of the cascade impactors operated from 7 to 16 May had a charcoal-impregnated final filter instead of the normal glass-fibre filter. Based on the 134I distributions on both charcoalequipped and normal impactors, we have estimated that ≤40% of the airborne ¹³¹I was aeorsol-associated. The actual fraction may have been smaller, as the efficiency of the filter for trapping gaseous 131I at high flow rate is not known. Both the Finnish and Swedish reports indicated that $\sim 15\%$ of the 13 I measured on 28 May was gaseous. If that fraction is applied to the Finnish data', the resulting ratio (1.0) agrees well with our aerosol "Cs/" I ratio from the 7-16 May measurement (0.89; see Table 1). Despite these qualifications, it is apparent that very little gas-to-aerosol transformation of [31] occurred during its transit to the United States.

Aerosol "I speciation was examined using methods previously applied to weapons fallout. The <0.41-µm aerosol ¹³I fraction, in both the 7-13 and 20-23 May measurements, consisted of $\sim 20\% I$. or I (or other CHC1, soluble species). No IO, was detected, in contrast to what was found for weapons-derived (ref. 4). The 0.41- to 0.73-µm fractions from these measurements showed similar CHC1,-soluble fractions.

Table 2 lists the mean aerodynamic sizes of aerosol-associated fission products reaching Tennessee. The fission product sizes increased considerably during the measurement period. By contrast, cosmogenic Be, which is initially associated with very small aerosols, is continually being added to the aerosol population. In the first two impactor measurements, ≤2% of the fission products were found to be larger than 2.1 µm, strongly suggesting the absence of any significant mechanical suspension of reactor material into the free troposphere. The behaviour and sizes of the fission products are consistent with the long-range transport of isotopes released by volatilization, which condensed on or with ambient or accident-produced aerosols. We did not find "Zr or rare-earth fission

products in our samples.

About 27% of the 144,147Cs and 46% of the Ru was not rapidly dissolved in cold 2M HC1. This behaviour is very different from what is observed for natural 'Be, Pb or 212Pb, which become associated with natural aerosols by surface condensation and are quite soluble. This poor solubility may indicate that some of the aerosol-associated fission products were

incorporated into reactor-derived materials which condensed in the hot plume leaving the reactor core. Autoradiographic evidence of such aerosols has been reported3.

Human lipocortin similar to ras gene products

SIR—Wallner et al. recently reported the sequence of a human lipocortin complementary DNA clone. We divided the predicted amino acid sequence of lipocortin into several fragments and, using the similarity matrix comparison program FASTP², the fragments were searched against each other in order to locate any regions of internal homology. Analysis of the computer alignments of the fragments, combined with visual alignment using the nucleic acid sequence as a guide, revealed that, except for the first 43 amino acids, the protein sequence is composed of four repeats (Fig.1). Statistical evaluations of all pairwise alignments of the repeats indicate a strong homology between most of them (Table 1). Com-

Table 1 Similarly scores (z) of the alignments of the lipocortin repeats

Α	В	z(s.d.)
I + II	III + IV	24.4
I	11	11.8
I	Ш	8.5
I	IV	11.4
П	Ш	9.3
П	IV	19.4
III	IV.	3.7

The FASTP program first identifies regions of sequence similarity, and then scores the aligned identical and differing residues in those regions by means of an amino acid replaceability matrix. The statistical significance of the alignment score between the repeat listed under A and the repeat under B is expressed as the similarity score (z), which is the number of standard deviations (s.d.) that the alignment score differs from the mean of the alignment scores obtained when A was compared to 100 random shuffles of sequence B. I + II and III + IV are amino acids 44-199 and 200-346, respectively. Scores between z = 3 and z = 6 are considered possibly significant, between 6 and 10 probably significant, and greater than 10 significant2,

[†] Based on four stages from two cascade impactors.

[‡] Aerosol ratio calculated from total 131 I, assuming 15% aerosol1.

Fig. 2 Alignment of the predicted amino acid sequences of human lipocortin and the human protooncogene e-K ras2a12. Identities are indicated by asterisks and favoured amino-acid substitutions by dots. Favoured amino-acid substitutions¹³ are defined by pairs of residues belonging to one of the following groups: S,T,A,G and P;N,D,E and Q;R,K, and H;M,I,L and V;F,Y and W.

parison of the nucleotide sequences of the four repeats, aligned as in Fig. 1, revealed 41% homology on average, with repeat II being 50% homologous to repeat IV. This suggests that the four repeats evolved from a common sequence by means of gene duplication events. To what extent these structural units are congruent with the functionally active fragments' lipocortin remains to be determined.

After original submission of this correspondence, Kretsinger and Creutz' described three regions in lipocortin which are homologous to a 17 amino acid consensus sequence" from nine peptide fragments of the four related proteins P36, pll, calelectrin and endonexin. The homologous areas of lipocortin that were identified by these authors are amino acids 56 to 72 in repeat I and the corresponding areas of repeats II and IV (Fig. 1).

To find additional homologies to other proteins, we searched the predicted amino acid sequence of lipocortin against 3,061 sequences in the Protein Sequence Database of the Protein Identification Resource (PIR)16. The FASTP program revealed a strong homology between lipocortin and the mammalian ras protooncogene products, which are thought to interact with phospholipase C in a Gprotein like fashion. The similarity score (z = 8.1 standard deviations) of the alignment between lipocortin and c-K-ras2a (Fig.2) is higher than the scores found by comparing ras to any of the known Gprotein sequences.

Evolutionary 'classics' may self-destruct

SIR-While respectively amused and bemused to see myself described as young, at 30, and as an entomologist, never having studied entomology, I feel compelled to comment on the further plethora of misinformation contained in Sibatani's recent letter', which attempted to defend the theory of evolution of Japanese scientist Imanishi against criticisms by Beverly Halstead2. At the outset let me make it clear that, contrary to Sibatani's implication in his final paragraph, my views on Imanishi's theory of evolution have not changed as a result of working with Kazumi Tanida nor do I retract any of the advice I gave to Beverly Halstead during his stay in Japan.

As the author and I have never met, the complete misrepresentation of my standpoint and persona are, perhaps, understandable. Unfortunately, the conclusions and arguments forwarded seem similarly based on a complete unacquaintance with the subject. Confusion regarding the concepts in question is evident, as typified by the paralogistic statement "... preferences may well partially overlap and are thus unlikely to explain the almost total segregation...observed...", and is also ap-

parent in the superficial dismissal of Halstead's supporting references. An informed reading of refs 3-5 will reveal them to demonstrate that groups of aquatic insects aggregate due to certain environmental and physical factors, and not due to any inherent species "protoidentity", as Imanishi would contend.

Reference 4 shows how selection of a physical variable by mayfly nymphs can "contribute significantly to the occurrence of highest densities on certain substrates and explain density shifts noted by other investigators in the field", thus adequately explaining Imanishi's wholly anecdotal field observations.

As only 0.3% of ref. 6 is concerned with "temporal segregation", it can hardly be said to "deal" with that topic, and in fact shows field and laboratory evidence of the importance of physical factors in the distribution of two sympatric trichopteran larvae. The extremely strictured rebuff, that physical preferences are accepted but may well overlap, seems to have been formulated in splendid detachment from harsh ecological reality. Rivers are not clinal continua and habitat quality can vary both temporally and spatially. Although various individual factors can affect life history parameters and maximize individual fitness". life history and distribution patterns usually represent a compromise between an interacting complex of biotic and environmental factors.

Competition itself is an interaction's. and so the attempted tautological evasion of the significance of the contents of ref. 7 fails, but does emphasize the need for a standardized definition of competition and its occurrence16

As for the quoted confirmatory evidence in the net-spinning Hydropsychidae", I feel that samples taken on only three occasions, two of which were 7 years apart, do not form an adequate logistic base for such conclusions, and the apparent loss of one species from the site during the sample period may actually provide evidence for competitive displacement or exclusion. Furthermore, in this family, the documented sequential downstream species-replacement, sometimes overlapping, sometimes disjunct, is well known12, detailed studies having revealed it to be mainly related to variations in the physical factor gradients down the length of a watercourse 12-15, while at the microhabitat level, species coexisting differed in their biotic and physical factor preferences, results agreeing with theoretical arguments based on resource partitioning16 and depressibility17.18. The regular spacing in some sites indicates territoriality, itself a form of intraspecific competition19. Larvae may fight for net sites and also possess an ultrasonic stridulatory mechanism which is used agonistically to repel intruders and to defend the site³⁶. In this family therefore, the evidence for

inter- and intra-specific competition is overwhelming and the distribution patterns are easily explained in terms of orthodox neo-darwinian theory. However, although a growing body of research has shown competition to play a critical role in determining habitat selection, survivorship and, ultimately, Darwinian fitness in some stream insects21, in other species, for example, mayfly larvae, little interspecific interaction was evident under certain conditions 12.23. There exist an immense variety of possible interspecific interactions, and dangers are inherent in overemphasizing any single aspect, and in overgeneralizing from observations taken either over a limited period. in a limited situation, or on a restricted range of species.

Scientific evidence should be based upon sound scientific data, and in this respect Imanishi's theory is found to be seriously wanting. Viewed from the ethereal realm of the philosopher, biological phenomena often differ in quite fundamental aspects than when viewed from the quantitative world of the scientist. Thus, Imanishi may have suffered the singular misfortune of basing his evolutionary theory upon non-quantitative observations made in a situation where little or no interaction occurred during the observation period. Such vague and essentially untestable theories are always difficult to disprove, but quantitative evidence usually eventually supercedes bad philosophy. As Wordsworth so eloquently phrased it, "Our meddling intellect misshapes the beauteous form of things", yet accuracy is the goal we seek. In this respect, the proposed translations of Imanishi's 'classics' may prove productive since, in addition to being "unrefined and crude"1, subjective analysis, coupled with the quantitative evidence from a growing body of research may reveal them to contain the ingredients of their own implausibility.

Recent discoveries of a supermass in the Universe

Sir-A pair of quasars with very similar redshifts was recently interpreted as a pair of images produced by a gravitational lens of enormous mass'. However, I and the other astronomers who originally discovered the quasars23 pointed out that this pair belonged to a tight association of five quasars on the sky. The spatial grouping alone was equivalent to a 20 sigma density enhancement. The similarities in redshift of these quasars — four were at redshifts z=0.9, 1.0, 1.0 and 1.1 — had in addition only a chance of $\approx 10^{-4}$ of being accidental. Later it was shown4 that all the densest concentrations of quasars known in the sky had this concentration of redshifts around $z \approx 1$.

For gravitational lens advocates to now fasten on certain aspects of only two obiects in these physical groups which fit their interpretation — and totally ignore the other information which does not fitis tantamount to distorting the scientific data.

The enormity of the derived mass also makes it clear that there is no result which is sufficiently absurd to force rejection of the original assumption. A scientific theory must be capable of being disproved which apparently this is not.

A fascinating sequel quickly emerges when it is shown that the two supposed images of the same object are not identical in the reds. The simple conclusion which follows is that these two quasars, which have almost identical spectra, are really two separate objects. But then what happens to the arguments for the original gravitational lens? (called Q0957+561; see refs 6-8).

The argument that it had to be a gravitational lens rested on the claim that there was no other explanation for how the spectra could be so similar. (Actually one was considerably redder than the other.) What is the evidence now for gravitational

In general we should not disguise the fact that gravitational lens theories are really just another variation of 'hidden mass' or 'dark matter' hypotheses. Just as undetected (or undetectable) matter is supposed to close the Universe, so unmeasured mass in clusters of galaxies is supposed to explain large redshift dispersions

and unseen and implausibly distributed mass is supposed to explain flat rotation curves in spiral galaxies. Until scientific detection and measures of these hypothesized entities is made they should be recognized as really just statements that some part of our current physical laws are contradicted by the observations.

Espresso coffee emporia take note

SIR—Apfel and Davy's report (Nature 321, 658; 1986) of the superheating of water by microwave ovens is totally consistent with empirical evidence obtained while using our laboratory microwave oven for preparing hot drinks (a practice sure to get us into hot water with our safety officer). I had placed a cup of tap water in the microwave and set it to boil but at first was prevented from making the drink by an experiment that required attention. On the third occasion of activating the oven, I responded to the timer bell by rushing to the oven, removing the cup and stirring my hot chocolate powder into the water which promptly erupted into a foaming cascade.

An interpretation of this dramatic event was that the water had become superheated and that the chocolate powder simply provided nucleation sites for the water to boil. In the light of Apfel and Davy's quantitative study of the superheating of water in microwave ovens it would seem that the explanation was correct. As well as offering supportive evidence and perhaps a cautionary tale, we think that a practical application of this phenomenon with coffee might be the production of energy-efficient espressos!

Tensions in science

David Dickson

Scientists and Journalists: Reporting Science as News.
Edited by Sharon M. Friedman, Sharon Dunwoody and Carol L. Rogers.

Free Press/Collier Macmillan: 1986. Pp.333. \$24.95, £25.

SHORTLY after taking over as the new administrator of the US National Aeronautics and Space Administration at the end of May, Dr James C. Fletcher delivered a stinging attack on the way that the US news media had covered the Challenger accident and its aftermath. Speaking to an audience of aerospace executives, he claimed that the media had acquired a "deep and unwarranted suspicion of NASA", reflected in its highly critical investigations of the agency's management, and that the resulting coverage could do "irreparable damage" both to the space programme and to the nation.

As several journalists were quick to point out, there was a certain irony in Fletcher's remarks. For NASA has always depended, perhaps more than any other US government agency, on heavy media coverage of its activities to generate the public enthusiasm needed to justify a continued investment of funds. Furthermore, studies of the agency's relations with the media in the 1960s suggest that a "myth of invincibility" had been deliberately developed, sustained by a lack of critical reporting, and became a factor in creating the conditions leading to the Apollo fire in 1969 in which three astro-nauts died.

Fletcher's remarks, however, highlight the ambiguity that surrounds public perceptions of science and technology in modern culture. Both are viewed as sources of trust and authority, but at the same time both are seen as containing threats that undermine the assumptions on which this trust is based. The ambiguity is reflected in two very different aspects of science journalism, and the tension between them emerges from a close reading of Scientists and Journalists, a collection of essays by working journalists, media sociologists and practising scientists.

The core of the book is a series of presentations delivered to a symposium organized by the American Association for the Advancement of Science. To these have been added further contributions which, while not exhaustive in their coverage (other views are referred to in a valuable annotated bibliography), nevertheless highlight many of the complexities of what is often considered a one-dimensional debate. Furthermore, although Scientists and Journalists is written primarily for an American readership, the perspectives on display are equally applicable to the practice of science journalism

in other countries, Britain in particular.

Several articles in the volume provide detailed accounts of the way that the different actors concerned with the communication of information about science see their professional responsibilities. An articulate statement of the journalist's role is provided by Christine Russell, a science writer on the Washington Post, while that of the public relations officer is described by Carol Rogers, who is responsible for such activities at the AAAS.

Other articles give insights either into the social factors that influence how science journalists operate as a community, or into the challenges to prevailing approaches to writing about science. In the first category Sharon Dunwoody, who teaches journalism at the University of Wisconsin, describes the existence of a "science writing inner club", made up primarily of experienced journalists from the main news media in the United States, and the way this "club" can influence what is treated as news by other science journalists. In the second category, Jon Franklin, a Pulitzer prize winner who writes for the Baltimore Evening Sun, tells how he has developed a highly-personal, narrative style of science writing. A closely annotated version of one of his essays, describing a surgeon's unsuccessful attempt to remove a brain tumour, provides useful hints for conveying scientific information in a readable and absorbing manner.

Taken together, these somewhat heterogenous contributions give a valuable overview of many of the issues that are likely to confront either journalists or scientists as each side struggles to make sense of the other.

At the same time, several of the authors address, sometimes only in passing, the question "where do we go from here?" And it is on this point that the tensions and disagreements arising from the ambiguities described at the beginning of this review begin to appear. For example, implicit in many of the contributions, as indeed in much of the current debate about the "public understanding of science" on both sides of the Atlantic, is that better science journalism will result from closer collaboration between scientists and journalists. Thus Dunwoody suggests the need to develop a "shared culture" of reporters and scientists which, she considers, has already developed from virtual non-existence to "a kind of fragile, neophyte state". Rae Goodell, however, a teacher of science writing at the Massachusetts Institute of Technology, uses an analysis of the recent controversy over the safety of recombinant DNA experiments to argue that an excessively close relationship can enable scientists to manipulate the media to their own advantage

Elsewhere, divergent views about the social function of science journalism reveal themselves as reflections of broader differences over desirable forms of social decision-making. Thus Jon D. Miller suggests that the main target for news about science, particularly those aspects relevant to policy issues, should be those at or near the top of the political tree. Under normal circumstances, he says, "I don't think any useful purpose would be served by directing policyrelevant information to the nonattentive segment of the public" (those he defines as lacking either a high degree of interest in science policy, or a "functional understanding of the process of terminology of science"). In contrast, David W. Crisp, a reporter for a local newspaper in Texas

NASA has depended on the media to generate public enthusiasm for its activities.

ASA

who won an award for his coverage of the federal government's proposal to build a nuclear waste dump near his town, describes how under certain conditions the science journalist can be thrust into the role of providing crucial information to those who might otherwise be deprived of it — or who distrust other sources.

Sadly, but perhaps wisely, the editors have not attempted to pull together the wide variety of points of view represented in the book. If they had done, they would have found considerable evidence to support the argument that a closer relationship between working scientists and journalists would undoubtedly be more comfortable for science. But whether it would necessarily be equally beneficial to the non-scientific community is less clear. As William Bennett, editor of the *Harvard Medical School Health Letter*, points out, the journalist's role of "informed sceptic" is vital to the health of a science-

based democracy. And this role is never a straightforward one; in science, even more than in politics or the arts, the definition of "informed" is often open to dispute.

Nevertheless scientists who are quick to attack critical reporting of their work, or that of their colleagues, should consider a thoughtful comment from David Crisp: "Good scientists and good journalists," says Crisp, "have a great deal in common: an ingrained skepticism toward established dogma, conventional wisdom and the tyranny of commonsense; an eye for accuracy and detail; the ability to deal impartially with facts that don't fit the theory; and contempt for the pernicious theory that all passionately held ideas are of equal value".

David Dickson, Le Billehou, 91190 Gif-sur-Yvette, France, is the European correspondent for Science, and the author of the New Politics of Science (Pantheon, 1984).

Dynamic insights

J.R.L. Allen

Coastal and Estuarine Sediment Dynamics. By Keith R. Dyer. Wiley:1986. Pp.342. £36, \$63.35.

SEDIMENT transport dynamics is of great importance in several disciplines, each of which, in its traditional garb, approaches the subject from a special standpoint and with particular perceived needs. This is why it is so hard to write about it well. Sedimentologists and geomorphologists are best able to discuss the outcomes of sediment transport, namely what, in the form of sedimentary textures, structures and larger scale formations, has to be explained. From fluid dynamicists and rheologists come the necessary theoretical and experimental insights into the roles of fluid motion and particle mechanics in sediment transport. Engineers, with their emphasis on an empirical, pragmatic approach, are best equipped to provide from contemporary environments and from the laboratory many of the additional links necessary for the appreciation of sediment transport and its real effects in quantitative terms.

Writing about sediment dynamics as expressed in shallow-marine environments, Dr Dyer rightly attempts to blend these three traditional approaches — sadly, still a rare venture. The result is a lucidly written book which, if with limitations here and there on the descriptive and theoretical sides, and a singular lack of photographic illustrations, is up to date and largely a success.

The book begins with a brief survey of the subject and a sketch of sediment production and the geological context of

modern shallow-marine sedimentation. Next come discussions of sediment particles as such and the fluid flow; more emphasis could usefully have been placed on the diversity and significance for transport of particle shapes, and on mass transport currents in waves. Chapter 3 covers sediment entrainment, one-way transport in suspension and as bedload, and bedforms (inadequately characterized). The following brief chapter examines sediment movement under waves, but the resulting bedforms are again ill-characterized and the origin of wave ripples is not explored. The further treatment of sediment suspension includes useful accounts of stratification by suspended particles and the suspension profile under waves.

In Chapter 7 Dyer compares sediment transport-rate formulae and sketches the important but under-researched topic of transport beneath waves and waves combined with currents. Not surprisingly, given the author's background, the treatment of cohesive sediments is excellent, except for the surprising omission of the by no means negligible mass-movement processes. Estuarine and coastal sedimentation are well summarized, as are beach processes, but the important role of storms in causing unusual sediment transport in these environments is ignored. An extensive bibliography (c. 1,000 items) and a short index conclude the book. Readers should beware equations 3.6 and 11.17, incorrectly set, and a mis-spelling of Bernoulli. Regrettably, SI units are eschewed.

This book has its faults. But it broadens our appreciation of sediment dynamics in shallow-marine environments, and deserves to be read and used.

Framework for twistors

Abhay Ashtekar

Spinors and Space-Time. Vol. 2 Spinor and Twistor Methods in Space-Time Geometry. By R. Penrose and W. Rindler. Cambridge University Press: 1986. Pp.501. £45, \$89.50.

Twistors were invented by Roger Penrose about 20 years ago. Since then he and his research group have worked on the subject steadily and have built it into a thriving branch of mathematical physics. The goal of the twistor programme is very ambitious - first to recast and then further develop all of known physics within a framework in which space-time itself is a derived, secondary object. Considering that relatively few individuals have been involved in the programme, the results to date are most impressive from a mathematical standpoint. Indeed, even if it should turn out that the ideas cannot be taken any further because of some intrinsic limitation, the fact that so much of the basic mathematical structure underlying relativistic physics can be constructed without a direct reference to space and time is, in itself, sufficient to make this endeavour fascinating. It is therefore regrettable that most mathematical physicists know virtually nothing about twistor theory. In part, this is because very little of the recent literature on the subject is accessible to non-specialists. The second volume of Spinors and Space-Time is intended to remedy this problem, and it does so very satisfactorily.

The authors first introduce the basic ideas of twistor theory, including some of the recent developments, and then go on to discuss a number of constructions of use in general relativity which are simplified and, in some cases, inspired by this theory. Since the relevant results and equations from Vol. 1 are recalled at the beginning of the book, readers familiar with 2-component spinors can go directly to Vol. 2.

The introduction to twistor theory is fairly detailed. Readers are first exposed to the non-local relation between the geometry of twistor space and of Minkowski space-time; they are then shown that the momentum angular-momentum structure of particles and fields can be coded in a natural way in the twistor picture; and, finally, they are presented with the description of the zero rest mass fields in terms of contour integrals and cohomology on the twistor space. It is remarkable that, although the relation between the twistor space and space-time is non-local, solutions to physically interesting local differential equations in spacetime can be represented in a natural way in twistor space. This interplay between cohomology on complex manifolds and solutions to differential equations on real manifolds is extremely interesting, because it brings together two otherwise unrelated branches of mathematics in an unexpected way. The outstanding application of these ideas to general relativity is the definition of quasi-local quantities which attempts to capture the notion of total energy-momentum and angular momentum associated with the region of space-time enclosed by a topological 2sphere. The current status of this definition and its consequences is described in detail. In addition, several mathematical results on null congruences, on algebraic classification of curvature tensors and on asymptotic structure of space-time at null infinity, which are simplified and illuminated by the use of twistor methods and the spin coefficient techniques, are presented in varying degrees of detail and completeness.

This is primarily a work in mathematics rather than physics. The emphasis is on illustration of the power and elegance of certain techniques rather than on provision of a comprehensive treatment of topics that are of direct application in general relativity. Consequently, the discussion is not uniform; points dealing with twistoral ideas and spin coefficient methods are treated thoroughly, while those requiring ideas from elsewhere are often mentioned only briefly.

Overall, there is a considerable difference between this volume and its companion. Volume 1 (reviewed in Nature 313, 607; 1985) appeared as a finished, definitive work that could be used in courses as well as by individual researchers. Volume 2, on the other hand, has a mixed flavour. Parts of it, such as the treatment of quasi-local mass, report the current state of the art. These parts have the style of lecture notes rather than that of a monograph. Furthermore, none of the chapters has an introductory section to map out the material that follows. Consequently, it is sometimes difficult to see where one is headed, and only those readers who are already familiar with more conventional treatment of topics such as gravitational radiation theory, and energy-momentum and angular momentum in general relativity, will be able to appreciate the simplifications and insights provided by twistor methods. Volume 2, therefore, is primarily for researchers who want to understand the spirit of twistor theory and for teachers of courses on general relativity who want to broaden their knowledge of the field.

Strategy for future weather

Nicholas A. Rupke

Climatic Change and World Affairs, Revised Edition. By Crispin Tickell. Center for International Affairs, Harvard University/University Press of America: 1986. Pp.76. \$17.50; pbk \$7.25. Distributed in Britain by Eurospan, 3 Henrietta Street, London WC2E 8LU. Hbk £16.55; pbk £7.30.

ERRATIC blocks and boulders, strewn across much of northern Europe and North America, reminded our ancestors of the waters of the biblical deluge. By around 1840, the Swiss naturalist Louis Agassiz concluded that these erratics had been put in place by gigantic ice sheets, and were evidence of a former Ice Age.

Heavy cloud in the southern hemisphere, as seen from Apollo 17. The photo extends from the Mediterranean to the Antarctic.

Thus began the scientific study of glacial climatic change in the geological past — change which, during the most recent, Quaternary Period of Earth history, has included half a dozen ice ages alternating with warmer interglacial stages. Simultaneously, however, our awareness of the vast extent of geological time has grown and, as a result, the historic reality of climatic upheaval has receded into the dim distance of "millions of years" before (or after) us.

Crispin Tickell's "brilliant short book" (to quote from Lord Zuckerman's introduction to the British edition) warns us, however, against a false sense of security and an après nous le déluge complacency. Our seemingly stable climate is in fact a vulnerable and changeable product of a

great many astronomical and terrestrial factors. Moreover, man himself has become a potentially destabilizing factor as a consequence of large-scale environmental mismanagement, such as the pollution of the air with carbon dioxide, aerosols and other industrial wastes which change the heat balance of our atmosphere.

Much has already been written about the threat to world climate - some authors demonstrating the scientific complexity and uncertainties of the issue, others giving free rein to doomsday predictions of imminent catastrophe in the form of a new and prolonged Arctic winter or, conversely, of the precipitous melting or surging of polar icecaps and a consequent rise in sea level. In this revised edition of a book first published in 1977 Tickell again succeeds in walking the tightrope between these two approaches: he presents an intelligible account of world climate in all its scientific complexity, but does so without letting the reader

lose a sense of the reality and potential immediacy of a calamitous deterioration. After all, only a relatively small change of a few degrees Celsius in mean global temperature would suffice to trigger an irreversible feedback process of glacial expanse or retreat at the poles.

The author (who is Permanent Secretary of the Overseas Development Administration in London) has examined the subject with the eyes of both science and international affairs. In a "call for action" he forcefully argues for the need to get some form of international agreement on how to cope with future climatic crises. More specifically, Tickell proposes that administrative responsibility be given to the World Cli-

mate Program (adopted in 1979 by the World Meteorological Organization) as the custodian of a series of climatic agreements. These should cover all major experiments and actions (industrial and military) which affect the climate. Furthermore, an international code of good climatic behaviour should be adopted and enforced by means of various economic measures.

Beginners and specialists alike will find Climatic Change and World Affairs lucid and stimulating, particularly if they are interested in science policy and international cooperation in the study of weather and climate.

Nicholas A. Rupke is a geologist and an historian of science at Wolfson College, Oxford OX2 6UD, UK.

Vegetative roots differ

Peter D. Moore

Studies on Plant Demography: A Festschrift for John L. Harper. Edited by James White. Academic: 1985. Pp.416. Hbk £45, \$59.50; pbk £22, \$29.50.

The Population Structure of Vegetation. Handbook of Vegetation Science, Vol.3. Edited by James White. Dr W. Junk: 1985. Pp.669. Dfl. 310, \$97.50, £85.95.

THROUGHOUT the history of plant ecology there have been profound disagreements over the most realistic, or at least the most intellectually profitable, way of studying vegetation. Is vegetation simply a "fortuitous juxtaposition of plant individuals", as maintained by Gleason? Or is it an orderly assemblage of recurrent plant associations, as conceived by certain schools of phytosociology? Plant population biology is essentially the product of an individualistic way of thinking: it is concerned with the interactions between adjacent members of a population, their growth, reproduction and mortality. But the overview of vegetation which the phytosociologist seeks to present must still recognize populations of plants, perhaps co-evolved, as the elemental structures from which higher levels of organization

Two approaches to the subject are thus possible: we can begin with vegetation and work down towards the individual, or we can begin with the individual in its population and gradually extend towards the more complex interactions of the community. In the books under review we find the two schools of thought effectively and separately illustrated, which is a credit to James White who edited both volumes.

John Harper, to whom the first book is dedicated in celebration of his sixtieth birthday, is rightly regarded as the founding father of plant population biology, and his perspective on the subject is essentially Darwinian and analytical; a view of architecture that begins with the

R.K. Peet has edited Plant Community Ecology: Papers in Honour of Robert H. Whittaker, which contains papers written by Whittaker's past colleagues and students after his death in 1980. Rather than review Whittaker's own contributions. Peet chose to illustrate current applications of approaches Whittaker developed and to show recent advances which have grown from his pioneering work. The papers are arranged in four sections, representing areas of plant community ecology which were strongly influenced by Whittaker: Methods of community analysis. Analysis of gradients, Community dynamics and Species Diversity. Published by Dr W. Junk as Vol. 7 of the "Advances in Vegetation Science". Pp.332. Dfl. 200, \$68, £55.50.

bricks. This collection of papers by his past students amply demonstrates the value of such an approach. Take John Ogden's work on forests, for example. In this type of habitat the long life-history of the individual gives an impression of stability, but population studies reveal a constant turnover, a mosaic of recovery stages from past disturbances — what Henry Horn has described as a "preemptive crazy quilt" of vegetation.

Mobility, of course, is a special problem for plants, but one that must be overcome if the patchwork of opportunities in the environment is to be fully exploited. Noble illustrates the effectiveness of birds in transporting seeds even when the birds in question cannot fly, as in the case of the gut carriage of *Nitraria* by emus in Australia.

Turkington, on the other hand, expands on the value of vegetative growth by stolons in clover. Clones can spread extensively in this way (some ecologists even talk of such plants "foraging"), but though the propagation of vegetative clones provides a form of mobility it can lead to a general lack of genetic diversity. In Turkington's view, the input of new genotypes by somatic mutation and occasional germination of new individuals is adequate to provide this required genetic variability.

Studies such as these on clover can lead to confusion about what really constitutes an individual plant. One approach is to consider a plant as a collection of relatively independent units. This idea of modular growth, where each module is the product of a single meristem, is particularly attractive and is exemplified here by Michelle Jones's report of her work on silver birch. In the case of trees, the branching systems differ in their "modular dynamics" because they are influenced by neighbours and respond by the formation of varying crown geometries. The implications of such studies for forestry are further developed by Miguel Franco.

The total collection of papers provides a wide range of examples from current studies in plant population biology. Most of these have originated from Harper's work and ideas, and are now taking root and ramifying.

In The Population Structure of Vegetation, James White is at pains to encourage the recognition of the complementarity of the demographic and sociological approaches. But it is vegetation that is quite recognizably the starting point of most of the papers included here, rather than population studies on individual species. Perhaps the key to the difference in thinking lies in the paper by T.A. Rabotnov on the dynamics of plant coenotic populations. But what, we may be forgiven for asking, is a coenotic population? It is defined as the sum of the individuals of a species within a plant community (the phytocoenosis), and is a concept arrived at by Rabotnov himself (the founding father of the Soviet plant coenotic population biology to whom this book is dedicated) as a result of the mental dissection of vegetation into its interacting components.

One of the consequences of this way of looking at population biology is the need to examine the demography of many different species at the same time; the detailed analysis of one species is of little value in isolation. Inevitably this leads to less-rigorous, less-numerical conclusions than typify the Harper school, but it also encourages the tendency to classify plants according to their interactive "strategies" as a means of simplifying community description. Some interesting proposals have resulted. The threefold classification of plants into "violents", "patients" and "explerents" by Ramenskii, for example, foreshadows the work of Grime, who also summarizes his current views in this volume. But such simple classification systems are not universally adopted by the contributors. Indeed, Grubb provides a detailed argument against the use of such models, demanding a much more critical attitude to the use of such terms as "stress", "tolerance", "dominance", "disturbance" and "competition", and calling for more attention to be given to the factors which permit coexistence among plants.

One prominent aspect of this book are the contributions of Soviet scientists, and Markov's paper on the use of permanent quadrats in the Soviet Union opens up for Westerners a useful window on Eastern ecology. Most of the Soviet papers are concerned with coenotic population research in steppic environments, but more occidental studies are also included, from chalk grasslands in the Netherlands to the cedar groves of the south-eastern United States. There are even some contributions that wander slightly from the "coenotic" theme, such as the demographic study of Plantago major and P. lanceolata by van der Aart. But even here the main emphasis is upon the variation in demography according to the plant's habitat - paths, hay fields, dunes, roadsides, pastures and so on — so the community remains the centre of interest.

Perhaps the most remarkable feature to emerge from these two books is the great difference in the starting point and the approach found in each and yet their tendency to generate lines of convergence. These lines will undoubtedly culminate in fruitful fusions, possibly under the diplomatic eye of James White, the sole common factor. Meanwhile, the balanced botanist must obviously have access to both.

Peter D. Moore is Reader in Ecology in the Department of Biology, King's College London (KQC), 68 Half Moon Lane, London SE24 9JF, UK.

What to believe about miracles

from R.J. Berry

Differences of interpretation within the Church of England have stimulated a re-examination of the "miracles" as recounted in the Bible.

Two years ago I was one of 14 signatories of a letter to the Times about miracles All of us were professors of science in British universities; six were Fellows of the Royal Society. We asserted: "It is not logically valid to use science as an argument against miracles. To believe that miracles cannot happen is as much an act of faith as to believe that they can happen. We gladly accept the virgin birth, the Gospel miracles, and the resurrection of Christ as historical events. . . Miracles are unprecedented events. Whatever the current fashions in philosophy or the revelations of opinion polls may suggest, it is important to affirm that science (based as it is upon the observation of precedents) can have nothing to say on the subject. Its "laws" are only generalizations of our experience...

A leading article in Nature accepting our statement on the nature of scientific laws, dissented from our conclusion about miracles, terming them "inexplicable and irreproducible phenomena (which) do not occur - a definition by exclusion of the concept. . . the publication of Berry et al. provides a licence not merely for religious belief (which, on other grounds is unexceptionable) but for mischievous reports of all things paranormal, from ghosts to flying saucers".

Subsequent correspondents disagreed. For example, Clarke objected that "your concern not to license 'mischievous reports of all things paranormal' is no doubt motivated in the interest of scientific truth, but your strategy of defining away what you find unpalatable is the antithesis of scientific"; MacKay4 emphasized that "for the Christian believer, baseless credulity is a sin - a disservice to the God of truth. His belief in the resurrection does not stem from softness in his standards of evidence, but rather from the coherence with which (as he sees it) that particular unprecedented event fits into and makes sense of a great mass of data. . . . There is clearly no inconsistency in believing (with astonishment) in a unique event so well attested, while remaining unconvinced by spectacular stories of 'paranormal' occurrences that lack any comparable support".

The credibility of belief in miracles has resurfaced in a report of the Church of England bishops⁵. The *Times* commented: "Did the two key miracles at the centre of the Christian faith, the Virgin Birth and the Resurrection, really happen?... The

that belief in miracles, at least where they are central to the faith, is thoroughly intellectually respectable. . . "6.

It would be easy to decry the criteria or standards of proof accepted by the bishops, but their integrity is presumably not in doubt. It is more profitable to enquire whether miracles are really credible, and, if so, what are the circumstances where they might be expected.

Natural law

"In an earlier age, miracles would have been one of the strongest weapons in the armoury of apologetic. A man who did such things must at the very least have the power of God with him. Jesus himself is represented as using this argument when he said, 'If it is by the finger of God that I cast out demons then the kingdom of God has come upon you' (Luke 11:20). For us today, by one of those twists that make up intellectual history, miracles are rather an embarrassment. We are so impressed by the regularity of the world that any story which is full of strange happenings acquires an air of fairytale and invention"7. The historical twist referred to by Polkinghorne was an inevitable consequence of the separation of observation (or test) from interpretation, which is the essential feature of what we call science. Before the sixteenth century "how" and "why" questions were answered in much the same way: acorns fell to the ground so that new oaks might grow; rain came so crops might flourish and people feed; and so on. The realization that the same event could be interpreted in more than one way led to an emphasis on mechanism, and therefore on the uniformity and predictability of natural events, with a consequent restricting of divine activity to the ever-decreasing gaps in knowledge. God became unnecessary, except as a rationalization for the unexplainable⁸.

By the seventeenth century scientists were using the "laws of nature" in the modern sense, and the physical and (increasingly) the biological worlds were regarded as self-regulating causal nexi. God was merely the "First Cause", and could intervene in the world only by breaking or suspending the "natural laws". Locke and Hume used the determinism of newtonian physics to argue that natural laws were inviolable, and therefore that miracles could not happen9. Their conclusion seemed to be vindicated exercise has established one thing clearly: I in the nineteenth century when the dar-

winian revolution purged from biological systems the simple notion of purpose and created pattern. And as Cupitt says, "religion was more badly shaken when the universe went historical in the nineteenth century than it had been when it went mechanical in the seventeenth century" The futility of believing in a god unable to do anything exposed the problem that spurred the English bishops to re-affirm that miracles could happen"

Miracles and mechanisms

Defenders of miracles have tended to descend into an unconvincing mysticism or an assault on determinism. A few decades ago, it was fashionable to claim that physical indeterminancy gave God enough freedom to control events. Biological indeterminancy is a live debate now, particularly in sociobiology. For example, Lewontin (unlikely to argue that miracles are common or important) strongly attacked the reality of biological laws beyond "very special rules of comportment or particular physical entities . . . If we are to find biological laws that can be the models for social laws, they will surely be at the level of laws of population. laws of evolution, laws of organization, But is is precisely such laws that are absent in biology, although many attempts have been made to erect them"

However, the case for miracles does not depend on indeterminancy, since the intellectual orthodoxy stemming from Hume's underlying thesis is not as strong as it is usually made out to be. C.S. Lewis pointed this out succinctly: "We must agree with Hume that if there is absolutely 'uniform experience' against miracles, if in other words they have never happened. why then they never have. Unfortunately we know the experience against them to be uniform only if we know that all the reports of them are false. And we know the reports to be false only if we know already that miracles have never occurred. In fact, we are arguing in a circle"

Exposing the fallacy of Hume's attack on miracles also reveals that it is based on an unjustified assumption, that events have only a single cause and can be fully explained if that cause is known. This is logically wrong. For example, an oil painting can be "explained" in terms either of the distribution of pigments or the intention and design of the artist; both explanations refer to the same physical object but they complement rather than conflict. In the same way, a miracle may be the work of (say) a divine up-holder of the physical world rather than a false observation or unknown cause. Such an interpretation does not depend on any irruption into a causal network, since the determinism of the machine is only one of the levels of the phenomenon (sensu Polanyi15).

'Complementary" explanations causation are excluded only by making the reductionist assumption that a single identifiable cause is the sole effect operating in a particular situation. This assumption is common, but unnecessary and restrictive. Medawar has dissected this clearly: "That there is indeed a limit upon science is made very likely by the existence of questions that science cannot answer and that no conceivable advances of science would empower it to answer. These are the questions that children ask — the 'ultimate questions' of Karl Popper. I have in mind such questions as: How did everything begin? What are we all here for? What is the point of living? Doctrinaire positivism — now something of a period piece — dismissed all such questions as nonquestions or pseudoquestions such as only simpletons ask and only charlatans of one kind or another profess to be able to answer. This peremptory dismissal leaves one empty and dissatisfied because the questions make sense to those who ask them, and the answers to those who try to give them; but whatever else may be in dispute, it would be universally agreed that it is not to science that we should look for answers. There is then a prima facie case for the existence of a limit to scientific understanding.

As far as miracles are concerned, this means that they are impossible to prove or disproye on normal scientific criteria; we accept the possibility of their occurrence by faith, and equally deny them by faith. Even if we know or deduce the mechanism behind a miracle, this does not necessarily remove the miraculous element. For example, the Bible tells us that the Israelites crossed the Red Sea dry-shod because "the Lord drove the sea back by a strong east wind all night and made the sea dry land" (Exodus 14:21); the significance of the miracle lies in its timing and place rather than its actual occurrence.

Implications

The act of faith that denies the possibility of miracles is a straightforward reductionist judgement. Miracles by themselves are always susceptible to an explanation other than the miraculous (even if they have physical manifestations, such as "spontaneous" healing or the Empty Tomb), so the value of the reductionist assumption can be best tested by its implications. These were spelt out with depressing clarity in the nihilism of Jacques Monod[®], and comprehensively answered by W.H.

dualism of Sherrington, Eccles and Popper which is kin to the complementarity espoused above19.

There are implications of embracing a reductionist determinism which impinge on two recent controversies: creationism and the definition of human life. Creationism is largely an insistence that God made the world in a particular way, without using "normal" evolutionary mechanisms. Part of this claim stems from a restricted interpretation of the Bible, but it has the effect of prescribing that God acted in an interventionist fashion. Notwithstanding, it is entirely consistent with both evolutionary biology and Bible texts to maintain that God worked "complementarily" with genetic processes so that the world is both a causal outcome of mutation, selection, and so on, but also a divine creation. The creationist position is at odds with both scientific and theistic understanding^{20,21}. Individual human life has a physiological and genetic continuity with that of other humans (and indeed, other animals); the value of individual life lies not in genetic uniqueness (cancers and hydatidiform moles are also genetically unique) but in being (in Christian language) "made in the image of God". This imago is not a physical entity, and it is a category mistake to confuse it with genetic coding or mental function. Notwithstanding, defenders of the inviolability of the early embryo make this precise mistake. The imago is a non-biological attribute, and there is no logical (or scriptural²²) reason for assuming that it is present from conception. If this simple point was realized, the ethical debate over developments in human reproduction could proceed more sensibly.

The conventional view of miracles is that they depend on supernatural intervention in, or suspension of, the natural order. Some theologians have been overimpressed with scientific determinism. and have attempted a demythologized (miracle-free) religion. This endeavour is now unfashionable, but it is worse than that; Nebelick called it "a speculativedevice imposed on unsuspecting persons. . . based on false presuppositions about both science and the scientific world view"23. This is no help to scientists, and an interventionalist God will always be an embarrassment to us.

I believe that the interpretation that miracles are a necessary but unpredictable consequence of a God who holds the world in being is more plausible and more scriptural than deist interventionism. This does not mean that apparent miracles should be approached with any less objectivity than we would employ for any scientific observation; our standards of evidence should be just as rigorous. Those who deny the possibility of miracles are exercising their own brand of faith; this is Thorpe who expounded a version of the | based on a questionable assumption, and |

one which creates problems with its implications. Miracles in the New Testament are described as unusual events which are wonders due to God's power, intended as signs. Confining oneself wholly to this category (leaving aside the question of whether other sorts of miracles occur), this makes at least some miracles expectable and non-capricious, and independent of any knowledge of their mechanism.

In his exposition of the "Two Cultures". C.P. Snow described the scorn of the one for the other as intellectual Ludditism²⁴. Miracles are examples of events which may easily be denied by an illegitimate reductionist Ludditism; scientific reality will be hindered in the process. A doctrinaire disbelief in miracles is not "more scientific" than a willingness to accept that they may occur. Some years ago Sir George Porter wrote: "Most of our anxieties, problems and unhappiness today stem from a lack of purpose which was rare a century ago and which can fairly be blamed on the consequences of scientific inquiry. . . There is one great purpose for man and for us today, and that is to try to discover man's purpose by every means in our power. That is the ultimate relevance of science"25. He was not writing specifically about miracles, but his argument applies. Miracles are not inherently impossible or unbelievable, and acceptance of their existence does not necessarily involve credulity, but does involve recognizing that science has limits.

Terrestrial origin of the Moon

A. E. Ringwood

Research School of Earth Sciences, Australian National University, Canberra, ACT 2601, Australia

Abundance patterns of siderophile elements in the Earth's mantle have been determined by complex processes connected with internal segregation of a metallic core amounting to 32% of the Earth's mass. Although the lunar core may be only 2% of the lunar mass and formed in very different conditions to the Earth's core, the lunar siderophile pattern is closely related to that of the Earth's mantle, implying that the material in the Moon derived mainly from the Earth's mantle after core formation. New models for the accretion of the Earth which require impacts by large planetesimals in the presence of a corotating primitive terrestrial atmosphere provide a mechanism for transferring material from the Earth's mantle into geocentric orbit as a ring of proto-lunar planetesimals, from which the Moon later accreted.

More than a century ago, Darwin¹ studied the tidal evolution of the Earth-Moon system and concluded that the Moon had been torn out of the Earth's mantle by a tidally induced fission process. Subsequently, it was realized that this would explain the anomalously low density of the Moon compared with the bulk Earth. Darwin's hypothesis enjoyed several decades of popularity before lapsing into obscurity after Jeffreys² had demonstrated that the proposed fission mechanism was physically unsound. Thereafter, it was generally considered that the low density of the Moon could be explained by an extension of the same processes responsible for causing marked differences between the intrinsic densities of the terrestrial planets (see refs 3, 4). Essentially, the Moon was regarded as having formed by processes analogous to those experienced by independent planets.

Jeffreys3, Urey4 and many others explained the intrinsic density variations between the terrestrial planets by assuming that they are composed of varying proportions of silicate (initial density, $\rho_0 = 3.3 \text{ g cm}^{-3}$) and nickel-iron ($\rho_0 = 7.9 \text{ g cm}^{-3}$) phases, each being essentially of constant composition. According to this model, Mercury and Mars contain ~65% and 20% of metal phase respectively whilst Earth and Venus possess intermediate metal contents. The model implies that the Moon contains <5% of metal phase. Urey^{5,6} proposed that physical processes occurring in the solar nebula before accretion of the planets had caused variable degrees of fractionation of iron particles from silicate particles in different regions of the nebula. Subsequent accretion of planets in particular regions reflected these pre-existing metal/silicate inhomogeneities. The major role attributed to metal/silicate fractionation in the solar nebula was supported by measurements which seemed to show that the abundance of iron in the Sun was lower by a factor of 5 than is found in Earth, Mars and chondritic meteorites. Urey's interpretation became widely accepted and has been reflected in subsequent cosmogonic models^{7,8}

Since 1959, I have argued that the mechanisms invoked by the above hypotheses to explain the metal/silicate fractionations were physically implausible and therefore attempted to develop a cosmogonic model aimed at minimizing the role of this process⁹⁻¹¹. The model proposed that the relative abundances of iron and the common lithophile elements (Mg, Si, Ca, Al) were the same in Mars, Earth and Venus, and were similar to those in the Sun and in chondritic meteorites. Differences in density between Mars, Venus and Earth were caused by differing oxidation states, a variable which was readily explained on cosmochemical grounds.

This interpretation received substantial support in 1969 when a more accurate determination of the relative abundance of iron in the Sun showed that it was similar to that in chondrites 12. Moreover, new space probe measurements have since provided precise values of the densities of Venus and Mars and of the martian moment of inertia. It was readily demonstrated that the gross physical (and chemical) properties of Venus, Earth and Mars were explicable in terms of models based on chondritic abundances of major elements, differing in mean oxidation state, with Mars being significantly more oxidized than Earth and Venus 11. The only planet displaying the effects of major metal/silicate fractionation is Mercury. Several authors have suggested that its high density, implying a high iron content, may be caused by specialized conditions of accretion, owing to its position nearest to the Sun 8,10.

These considerations have an important bearing on the origin of the Moon. During the period 1950-70, most scientists treated the Moon as representing an extreme case of the general process of iron/silicate fractionation which was believed to have occurred between Sun and planets, and between the planets themselves. In this sense, it was regarded as an 'independent planet', which, owing to special circumstances, had accreted in orbit around the Earth or had been captured into Earth orbit.

However, we now recognize that the Moon must have accreted in a region of the Solar System between Earth, Mars and Venus, and probably close to the Earth. Currently, there is no evidence requiring iron/silicate fractionation between these planets and the Sun. From this perspective, the high depletion of metallic iron in the Moon must be recognized as a truly remarkable phenomenon. This led me in 1960 to revive Darwin's hypothesis that the material now in the Moon was derived from the Earth's mantle by a fission process, albeit employing a different mechanism¹³ from that proposed by Darwin. Analogous fission-related hypotheses were also developed during the 1960s by Wise¹⁴, Cameron¹⁵ and O'Keefe¹⁶. Subsequently, I abandoned the fission mechanism and developed another model in which the Moon was formed from material evaporated from the Earth's mantle in a high-temperature regime caused by rapid accretion of the Earth^{10,11,17-19}.

If the Moon were indeed derived from the Earth's mantle, one might hope to find supporting evidence in a comparison of the chemical compositions of both bodies. Unfortunately, there are divergent views among geochemists regarding the major element composition of the Moon. Some believe that the Moon's composition is similar to that of the Earth's upper mantle 11,20,21, whereas others 22,23 believe that refractory elements are markedly

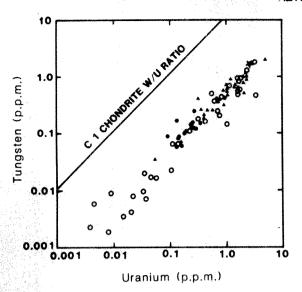

Fig. 1 Tungsten (siderophile) and uranium (lithophile) concentrations in terrestrial and lunar rocks. ○, Earth's mantle; ★, upper crust; ♠, lunar mare; ♠, lunar highlands. The W/U ratios in both bodies are remarkably similar despite the fact that core formation within the Earth caused tungsten to be relatively depleted in the upper mantle by a factor of ~25 compared with the primordial C1 W/U ratio (solid line). The lunar samples include both mare and highland rocks, showing that the lunar W/U ratio is of global significance. (After refs 33, 49, 52.)

enriched in the Moon. But is there any other source of compositional evidence which points unambiguously towards a terrestrial origin? I believe that the answer is provided by the siderophile geochemistry of Earth and Moon.

Siderophile geochemistry

The abundance patterns of siderophile elements in the Earth's mantle display some remarkable characteristics. For example, Ni, Co, Cu, Fe, Ga, W, Mo, P, As, Sn, Ag and Ge are present at levels ranging between 1 and 16% of their primordial abundances^{24–28}. Little relationship exists between the partition coefficients for these siderophile elements between silicate and metallic iron phases, and their relative abundances in the mantle. The platinoids, Au, Re, S, Se and Te, are present in the mantle at $\sim 0.3\%$ of their primordial abundances^{25,27–29}. Most of the above siderophiles are considerably overabundant in the mantle compared with expectations based on experimentally determined partitions between silicate and metallic iron phases.

Chromium and vanadium, which display distinct siderophile tendencies above 1,500 °C (refs 30, 31), are significantly depleted in the mantle by factors of 2 and 1.5, respectively²⁵. These depletions almost certainly reflect their partial entry into the core³². Manganese also displays a fourfold depletion which may be caused either by entry into the core^{20,32,33} and/or by loss due to volatility²⁴.

The above patterns have evidently been caused by a combination of several complex processes, as yet incompletely understood, which occurred during the segregation of a metallic core, amounting to 32% of the Earth's mass. Partitions of siderphiles would have been affected by the very high pressure (P) and temperature (T) regime under which this process operated, and by the presence in the core of $\sim 10\%$ of light elements, probably consisting mainly of oxygen³⁴. It is also widely believed that the terrestrial siderophile pattern was substantially influenced at an advanced stage of accretion by the physical mixing into the mantle of an oxidized, solar nebular condensate in conditions which did not permit equilibration with metal phase $^{20,27-29}$.

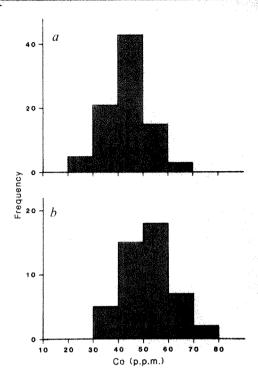

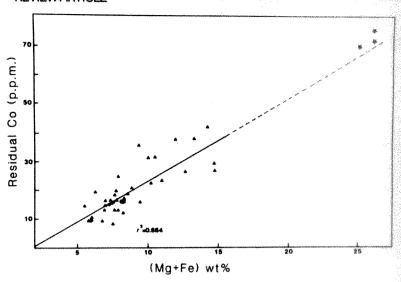

Fig. 2 Comparison of Co abundances in terrestrial oceanic tholeiites (a, mean Co = 43 p.p.m.) and in lunar low-Ti mare basalts (b, mean Co = 51 p.p.m.) (from ref. 53).

The particular combination of processes which generated the siderophile signature of the Earth's mantle probably did not operate to the same extent in all planets and differentiated planetesimals. Accordingly, it is expected to be unique to the Earth, or to an Earth-like planet. This expectation can be tested by comparing the terrestrial siderophile signature with the siderophile signature of the parent body of shergottites35-38 which is widely identified as Mars^{39,40}. As with the Earth, most siderophiles (such as, Co, Ni, P, W, Ge, Mo, Au and Ir) are substantially overabundant compared with expectations based on equilibrium partitions between silicate and metallic iron phases. There are, however, very significant differences between the martian and the terrestrial signatures. In shergottites, W and P are present at levels about 5-10 times higher than the Earth, while Cu, Ni, As, T1 and In are depleted by factors of 5-20. Moreover, Mn and Cr are present in primordial C1 abundances, whereas these elements are depleted in the Earth. In addition, the oxygen isotope composition of shergottites is significantly different from that of the Earth 41,42. Dreibus and Wänke 36 have pointed out that the differences between the martian and terrestrial siderophile signatures could be explained by differences in the mode of accretion of both planets, combined with the presence of a large quantity of sulphur in the martian core.

The siderophile signature displayed by the silicate phase of the eucrite parent body (EPB) differs in turn from those of the Earth and Mars. In this case, the siderophile abundances reflect a close approach to chemical equilibrium between silicate and iron phases during segregation of the core in the EPB. In consequence, many siderophiles (for example, Ni, Co, Cu, Ga, Mo and Ir) are relatively depleted by factors varying between 3 and 50 in the EPB silicate phase compared with the Earth's mantle⁴³⁻⁴⁵. On the other hand, Mn, V and Cr are present in primordial abundances, in contrast to their depletion in the Earth's mantle^{32,43}.

The above discussion highlights the unique nature of the siderophile signatures in the mantles of planets and planetesimals which have differentiated to produce substantial metallic cores. The siderophile signature of the Moon, in which

Fig. 3 Cobalt in primitive lunar volcanic glasses (★) and Apollo 16 highland breccias (▲, corrected for meteoritic contamination) plotted against (Mg+Fe). Note that the solid line representing the best fit to the highland breccia data projects directly into the field of primitive volcanic glasses, showing that the lunar Co/(Mg+Fe) ratio is of global significance. (After ref. 53.)

a metallic core probably amounts to <2% of its mass, is therefore likely to be of considerable interest.

Lunar siderophile signature

The importance of lunar siderophile geochemistry to the problem of the Moon's origin was emphasized by O'Keefe⁴ O'Keefe and Urey47. A comparative study of siderophile abundances in terrestrial and low-Ti lunar basalts, carried out by Ringwood and Kesson", concluded that the average abundances of a particular group, including Fe, Co, Ni, W, P, S and Se, were similar within a factor of ~2. Pointing to the unique factors responsible for the siderophile signature of the terrestrial mantle and its derived basalts, they concluded that "the similarity in siderophile elements between the Moon and Earth's mantle therefore implies that the Moon was derived from the Earth's mantle after the Earth's core had segregated". They also recognized that another group of siderophiles (Ga, Cu, Ge, As, Ag, Au, Sb, Re) was genuinely depleted in the Moon compared with Earth and ascribed this to loss as volatile species. Delano and Ringwood⁴⁴ made a parallel study of the siderophile chemistry of lunar highland breccias, after applying corrections for meteoritic contamination. They found that the indigenous siderophile signature in the lunar highlands closely resembled that of the low-Ti mare basalts and terrestrial basalts, thereby reinforcing the previous conclusion.

Wänke and co-workers in Mainz independently arrived at very similar conclusions^{48,49}, based on detailed studies of the geochemical behaviour of W and P in terrestrial rocks and in lunar highland rocks and basalts (Fig. 1). Wänke et al. 50,51 extended these conclusions by demonstrating the occurrence of a substantial component in the Apollo 16 highlands breccias. possessing very similar Ni/Mg and Co/Mg ratios to the Earth's mantle. Wänke and Dreibus 20,32,33 also drew attention to the genetic significance of similar Cr, V and Mn abundances in the Moon and in the Earth's mantle. As noted earlier, these elements are significantly depleted in the mantle, primarily because of their partial entry into the Earth's core. Wänke et al.50 also recognized that another group of highly siderophilic elements was depleted in the Moon compared with the Earth's mantle. They attributed this depletion not to volatility (as proposed by Ringwood and Kesson²⁴) but to selective extraction by segregation of a small metallic core within the Moon.

Tungsten and cobalt provide good examples of moderately siderophilic elements whose geochemical behaviour in the Earth are well understood. In oxidized form, W is an incompatible element and behaves similarly to U during magmatic fractionation. Hence the W/U ratio in terrestrial rocks remains approximately constant over a wide concentration range (Fig. 1)^{33,49,52}.

Tungsten and uranium are both refractory elements and were accreted by the Earth in chondritic relative abundances 23,49. Because of its siderophile nature, W was depleted in Earth's mantle by a factor of 25 owing to its entry into the Earth's massive core. The W/U ratios of lunar mare and highland rocks are almost identical to those of terrestrial rocks (Fig. 1). In view of the similar U abundances in the Earth's mantle and Moon¹¹, the W abundances in both bodies must display a corresponding similarity.

Unlike W, Co is a compatible element which is not strongly fractionated (relative to Mg and Fe) during magmatic differentiation. Abundances of Co in terrestrial tholeittes and lunar low-Ti mare basalts are shown in Fig. 2 and are very similar^{24,53}. Figure 3 demonstrates a good correlation between Co and (Mg+Fe) in lunar highland breccias. Moreover, the highland Co/(Mg+Fe) ratio is identical to that displayed by the least fractionated lunar mare basaltic magmas as represented by volcanic glasses, confirming that the lunar Co/(Mg+Fe) ratio is also a global characteristic. Experimental investigation⁵³ of the distribution of Co between a primitive lunar volcanic glass, liquidus olivine and metal phase confirmed that the Co content of the lunar mantle was very similar to that of Earth's mantle.

The conclusion by both Canberra and Mainz groups that the similarity in abundances of a particular group of siderophile elements in the Earth's mantle and Moon unequivocally implies that the material in the Moon has been derived from the Earth's mantle created considerably controversy. Most lunar scientists were reluctant to accept the proposition that the vexed question of the Moon's origin could be settled by such a 'simple' argument. Nevertheless, the controversy had beneficial results because it stimulated the acquisition of additional analytical data on the abundances of siderophile elements in lunar and terrestrial rocks, and on partition coefficients of siderophiles between metal and silicate phases. The demonstration⁵² that molybdenum was depleted in the Moon by a factor of ~30 was particularly significant, since the depletion of this highly siderophilic element could not be ascribed to volatility, and pointed towards extraction by a small metallic lunar core⁵

The new data have been combined with earlier results in Fig. 4 as a plot of abundance ratios of siderophile elements in the Earth's¹¹ mantle and Moon verus their metal/silicate partition coefficients. Analogous but less comprehensive diagrams have been constructed by Wänke and Dreibus³³ and by Newsom⁵². It is seen that the abundances of elements less siderophilic than nickel (Mn, V, Cr, Fe, W, Co, P, S, Se) are similar (within a factor of 2) in both bodies. Elements more siderophilic than nickel (Cu, Mo, Re, Au) are depleted to degrees which correspond well with their metal/silicate partition coefficients. Nickel

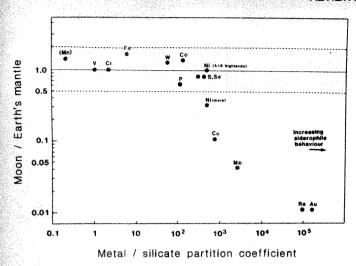

Fig. 4 Abundance ratios of siderophile elements in the Moon and Earth's mantle versus their metal/silicate partition coefficients. Partition coefficients used for compatible elements, Mn, V, Cr, Fe, Co and Ni, are based on measured distributions between olivine and Fe-metal phases^{30,31,53,79}. Partition coefficients for generally incompatible elements W, P, S, Mo, Re and Au, are for basaltic melts and Fe-metal phases^{40,80-83}. Positions of Se and Cu were estimated by interpolation from the free energies of formation of their oxides. Abundance data for siderophile elements in the Moon and Earth's mantle are from the following sources: Mn, refs 24, 25; V, Cr, refs 24, 25, 79; Fe, refs 24, 25; W, refs 24, 25, 49, 52; P, refs 24, 25, 33, 44; Co, refs 24, 25, 53; S, Se, ref. 24; Ni, refs 50, 53; Cu, refs 24, 25; Mo, refs 27, 52; Re, Au, refs 24, 29, 84, 85. Brackets around Mn indicate the possibility that its depletion in the Moon and Earth might be related to volatility rather than siderophile behaviour²⁴.

presents an interesting case and has been studied extensively; it is depleted by a factor of ~ 3 in the source regions of the most primitive lunar basalts^{33,53-55} but is present in terrestrial abundances (relative to Mg) in breccias at the A16 lunar highlands site^{50,53}.

Wänke and colleagues^{33,50,52} have shown that the depletions (below terrestrial levels) of highly siderophilic elements shown in Fig. 4 can readily be explained by separation of a small metallic core amounting to <1% of the lunar mass. This would not markedly affect the abundances of moderately siderophilic elements but would have strongly depleted the highly siderophilic elements. The presence of a small (<2% by mass) lunar core is strongly suggested by the lunar moment of inertia coefficient⁵⁶ ($I/MR^2 = 0.391 \pm 0.002$) and by the observation of a phase shift in the forced precession of the lunar figure⁵⁷.

The composition of the lunar core is constrained by the nickel and cobalt abundances of lunar mantle silicates. The nickel content of the lunar mantle can be determined using a procedure identical to that used to determine its abundance in the Earth's mantle, that is by measuring the nickel content in the olivine crystallizing on the liquidus of the most primitive, unfractionated basaltic magmas derived from the lunar interior. Ringwood and Seifert⁵³ used this technique to demonstrate that the olivine of the lunar mantle contains ~900 p.p.m. Ni. Moreover, they showed that any metal in equilibrium with lunar olivine would contain at least 40% nickel. It is reasonable to expect that lunar mantle silicates would have equilibrated with metal phase during segregation of the lunar core. Thus the lunar core is required to contain at least 40% Ni in sharp contrast to the Earth's core, which contains ~5% Ni (ref. 53). An analogous technique has been applied⁵³ to a totally independent data-set to demonstrate that the cobalt content of the lunar core is also higher than that of the Earth's core. The gross dissimilarities in chemical compositions between the lunar and terrestrial cores have important implications for hypotheses of lunar origin.

Implications for lunar origin

Previously, it was shown that the lunar and terrestrial siderophile signatures differ fundamentally from those of the shergottite parent body (Mars) and the EPB. The reasons why the terrestrial siderophile signature is likely to be unique to the Earth or an Earth-like planet have also been documented. Figure 4 provides a striking illustration of the close relationship between the abundances of siderophiles in the Earth's mantle and the Moon. The moderately siderophile elements in the Moon are clearly 'Earth-like'. Although the highly siderophilic elements are greatly depleted in the Moon compared with Earth, this can be readily explained by segregation of a small amount (<1%) of a Ni-rich metal phase (~40% Ni) from parent material of terrestrial composition to form a lunar core. I conclude that the close relationship between the lunar and terrestrial siderophile signatures depicted in Fig. 4 provides definitive evidence for the terrestrial origin of the Moon, as argued previously by the Canberra and Mainz groups. This is further supported by the identity in oxygen isotope compositions between Earth and Moon and their dissimilarity with those of shergottites and differentiated meteorites41,42

Could these abundance patterns be explained in terms of an origin of the Moon as an "independent planet" 23 ? Newsom 52 has attempted to show that the lunar abundances of W, P, Ni and Co could be explained by this hypothesis. His model requires the separation within the Moon of an iron-rich metallic core amounting to $\sim 5\%$ of the lunar mass. The model can be rejected on the following grounds.

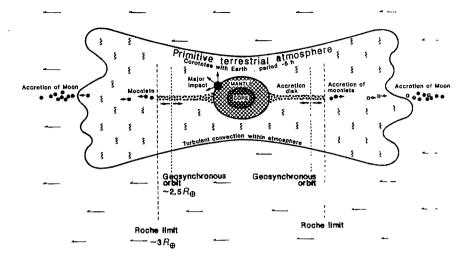

- (1) Current geophysical and petrological models of the Moon agree that its FeO content lies between 8 and 17% (refs 21, 50). If the lower limit is accepted, an iron core amounting to 5% of the lunar mass would lead⁵⁸ to a mean lunar density exceeding 3.40 g cm⁻³ in contradiction to its observed density of 3.34 g cm⁻³. The discrepancy is increased if the more widely accepted estimate of 13-16% FeO in the lunar mantle is used. (2) Experimental data cited previously show that the lunar core is Ni-rich; this causes a decrease in the effective metal/silicate partition coefficients for W (ref. 49), p (ref. 59) and Co (ref. 53) as compared with pure iron. Newsom's model therefore requires a metal core constituting substantially more than 5% of the lunar mass.
- (3) The size of the lunar core is constrained to be <2% of the lunar mass by the seismic observations of Nakamura *et al.*⁶⁰ who state that "the radius of a low-velocity (molten) core cannot be greater than about 350 km because normal transmission of P waves to that depth is observed".
- (4) The model fails to explain the similar abundances of Mn, Cr, V, S and Se in the Moon and the terrestrial mantle (Fig. 4) and their variable depletions as compared with primordial abundances.

More generally, the 'independent planet' hypothesis of lunar origin encounters a series of additional difficulties, which cumulatively are quite lethal.

- (i) The siderophile signature of the terrestrial mantle was established by a series of complex processes occurring during the segregation of a large (32% $M_{\rm E}$) metallic core within the Earth. If the Moon had formed as an independent planet, it would be quite incredible if its very different conditions of accretion, followed by segregation of a relatively small ($\sim 2\% M_{\rm m}$) core possessing a composition grossly different to the Earth's core, and formed in a totally different P, T environment, had, nevertheless, produced a siderophile signature similar to the Earth's mantle.
- (ii) The dilemma of providing a plausible mechanism for explaining the depletion of iron in the Moon, as compared with Earth, Venus and Mars, is not resolved.
- (iii) Previous attempts to solve this problem have relied on

- Solar nebula (mainly H2)

Fig. 5 Model showing the formation of the Moon via the ejection of material from the Earth's mantle by impacts from late-accreting planetesimals in the presence of a corotating primitive terrestrial atmosphere.

highly speculative physical mechanisms to fractionate metal from silicate in the nebula, before accretion of the Moon⁶¹. However, in these models, the composition of the metal phases accreted by Earth and Moon would be similar, that is Fe-rich and Ni, Co-poor. This is contrary to the evidence cited previously that the lunar core is actually Ni, Co-rich and quite different in composition to the Earth's core.

(iv) Some workers⁶² have attempted to interpret the Moon as having formed from an earlier generation of planetesimals which accreted in the solar nebula and then melted and differentiated analogously to the eucrite parent body. These were subsequently fragmented and their metal cores somehow removed, leaving the Moon to accrete from the differentiated silicate mantles. The major differences already noted between the siderophile signatures of the Moon and the silicate phase of the EPB are unexplained by this model. Moreover, the mechanisms proposed for removing the metal cores are highly implausible^{63,64}.

Making of the Moon

The geochemical evidence reviewed previously can apparently only be satisfied if the Moon was formed from material derived from the Earth's mantle after the core had segregated. Provision of the energy and angular momentum required to remove >1% of the Earth's mass and place it into orbit represents a rather formidable challenge. For two decades, I have argued that the energy was provided by the Earth's own gravitational energy of accretion and that the requisite angular momentum was transferred from the rapidly rotating Earth to protolunar material by a corotating primitive terrestrial atmosphere.

According to these models 10,11,17-19, accretion of the Earth

occurred before dissipation of the primordial gases of the solar nebula. Accretion was accompanied by the formation of a primitive terrestrial atmosphere comprised mainly of hydrogen gravitationally captured from the solar nebula⁶⁵⁻⁶⁷. The primitive atmosphere was coupled to the Earth's rotation through turbulent viscosity and hydromagnetic torques and was thereby spun out into a corotating disk (period ~5 h). During the later stages of accretion of the Earth, high temperatures were produced by a combination of rapid accretion and thermal insulation by the primitive atmosphere. In these conditions, material from the mantle was evaporated into the primitive atmosphere and spun out into the disk. As the primitive atmosphere cooled and was dissipated, the silicate components were precipitated to form a ring of Earth-orbiting planetesimals. Further fractionation due to volatility occurred during the precipitation process, since the more volatile components would be precipitated at relatively low temperatures, forming micrometre-sized smoke particles. These remained coupled to the escaping gases and hence were removed from the system. The Moon accreted from the ring of devolatilized Earth-orbiting planetesimals.

The principal problem with this scenario was the short timescale (~106 yr) over which the Earth must have formed if the gravitational potential energy of impacting planetesimals was to have generated the sustained high temperatures necessary to evaporate part of the upper mantle during the late stages of accretion. An attractive alternative is provided by the models of Hartmann and Davis⁶⁸, and of Cameron and Ward⁶⁹. These authors invoke one or a few impacts by giant, late-accreting planetesimals to evaporate material from the Earth's mantle and place it into orbit. The planetesimals are believed to have sizes ranging between a substantial fraction of the lunar mass and the size of Mars⁷⁰. The physical processes envisaged⁷¹ are quite closely related to those of my earlier models. Rather than achieve high mantle-evaporation temperatures via the 'steady-state' liberation of gravitational potential energy from a continuum of relatively small impacts over a short accretion timescale (1 Myr), giant impact models achieve these conditions in one or a few transient ultrahigh energy events, and permit a much longer accretion timescale for the Earth (such as 10^7-10^8 yr).

Although the giant impact model is currently attracting considerable interest, it is not free from potential problems. It is expected to lead to complete melting of the entire Earth^{70,72}, this should have caused efficient differentation of the mantle accompanied by formation of a massive 4,500-Myr terrestrial crust, contrary to observation¹¹. Complete melting of the Earth and subsequent crystallization of the mantle should also have been accompanied by near-quantitative degassing of volatiles such as CO₂, N₂, Cl and inert gases. This implication is not readily reconciled with available geochemical evidence^{4,5,73}.

Accordingly, I now prefer a model intermediate between my earlier rapid-accretion models and the current giant impact models (Fig. 5). A key role in lunar genesis continues to be played by the primitive terrestrial atmosphere which corotates with the Earth, extending as a disk perhaps out to 5 Earth radii $(R_{\oplus})^{65,74,75}$. The atmosphere would extend the effective radius of capture of incoming planetesimals. This factor might have contributed to a relatively short rotation period for the Earth.

During most of the Earth's accretion, small planetesimals would be captured by the atmosphere and would spiral down to the equatorial plane, forming an accretion disk. Large planetesimals would impact the Earth directly; their ejecta would be captured by the atmosphere and transferred to the accretion disk. Within the disk, planetesimals orbiting inside the geosynchronous limit would experience gas drag and spiral

inwards to the Earth. Beyond the geosynchronous radius, the atmosphere, coupled to the Earth by hydromagnetic torques, would be rotating faster than the keplerian velocities of the planetesimals, which consequently would be driven outwards. However, as the mass of the Earth continued to grow by accretion, the geosynchronous orbit expanded so that most of this material was eventually accreted by the Earth.

It is possible to form the Moon only at a late stage of accretion when the Earth had developed nearly to its present size and core formation was complete (or nearly complete). At this stage, impacts of many large (100 < R < 1,000 km) but not necessarily giant (R > 1,000 km) planetesimals at velocities exceeding 12 km s⁻¹ would vapourize ~5 times their own mass of target material and would shock-melt 100 times their own mass⁷⁶. The shockmelted material would probably form a spray of devolatilized droplets. Rapid expansion of the impact cloud would cause acceleration to high velocities^{70,71}. As the cloud expanded and cooled, selective condensation of the less volatile components would have produced more liquid droplets which subsequently solidified. Highly volatile elements condensed only at relatively low temperatures, forming smoke particles.

The corotating primitive atmosphere is believed to have had an essential role in transferring angular momentum from the solid Earth to impact-evaporated gases and liquid spray, so that a substantial proportion of the ejected material was placed in circular, equatorial orbits. The devolatilized droplets.(1-10 mm) and coarser condensates accreted to produce an assemblage of devolatilized planetesimals. Most planetesimals probably

accreted in orbits smaller than the geosynchrous limit ($\sim 2.5~R_{\oplus}$ for a rotation period of 5 h). They would have lost energy through dissipation in the corotating atmosphere and hence spiralled back to Earth. However, a significant proportion of planetesimals would have been formed beyond the geosynchronous limit. They would have been accelerated by gas-drag. causing them to spiral outwards, beyond Roche's Limit $(\sim 3 R_{\oplus})$. Here they would have accreted into moonlets, which continued to spiral outwards (through gas drag) to the boundary region between the corotating primitive terrestrial atmosphere and the solar nebula. Accretion of moonlets to form the Moon occurred in this region, possibly at a distance of \sim 5 R_{\oplus} (Fig. 5).

It remains to consider the significance of the higher FeO content of the Moon compared with the Earth's mantle^{54,75}. Actually, the Mn (ref. 24), Co (ref. 53) and W (ref. 33) abundances in the Moon may also be slightly but significantly higher than in the Earth's mantle (Fig. 4). It has been suggested 33,77 that the excess FeO was derived from planetesimals involved in the major impacts. This explanation might apply also to the excesses of Mn, Co and W. The planetesimals accreting at a late stage on the Earth may well have been oxidized, containing no free metal phase⁷⁸. The excess Fe, Mn, Co and W might be explained if the impact ejecta included ~20% of the projectile, Under the high temperatures pertaining, a limited degree of autoreduction is likely to have occurred, yielding ~1% of Nirich metal phase which ultimately segregated to form the lunar core.

Primordial density fluctuations and the structure of galactic haloes

P. J. Quinn*†‡, J. K. Salmon†‡ & W. H. Zurek‡

N-body models used to study the formation of structure in $\Omega=1$ universes reveal that the mass profiles of the collapsed structures—galactic haloes—are intimately related to the power spectrum of initial, gaussian, density perturbations. In particular, flat rotation curves observed in disk galaxies are obtained only when the exponent of the power law $P(k) \sim k^{\circ}$ is, on the megaparsec scale, less than -1, but not as small as -3. These results have important implications for various cosmological models.

THE structures observed in the Universe on the galactic and larger scales are believed to have been seeded by primordial density perturbations¹. These perturbations were presumably imprinted much earlier by a process such as inflation²⁻⁴. Later, they were modified in the course of the radiation-dominated era (redshift $z > 2.5 \times 10^4 \Omega h^2$). Both this initial imprinting, and the more recent modifications depend sensitively on the composition of matter in the Universe and on the physics at very high energies. Therefore, an understanding of the formation of structure from initial, seed perturbations is essential for cosmology as well as for particle physics.

We now explore, by means of computer modelling, the formation of collapsed and virialized structures in Einstein-deSitter $(\Omega=1)$ universes. We focus on a class of model universes characterized by gaussian, scale-free density perturbations. Their power spectra:

$$P(k) = Ak^n \tag{1}$$

are completely specified by the normalization constant A and the exponent n. k is the wavenumber. The white noise case corresponds to n=0. Scale-free perturbations in an $\Omega=1$ universe result in hierarchical clustering⁵⁻¹⁰, which is both reasonably easy to analyse and often a good approximation of more complicated and more realistic models. We shall also simulate the formation of haloes in CDM (cold dark matter) universes¹¹⁻¹³. Indeed, we shall normalize our scale-free power spectra so that on a 'galactic scale' they have similar power to the CDM case. The influence of Ω on the structure of galactic haloes will be treated elsewhere (W.H.Z., P.J.Q. and J.K.S., manuscript in preparation).

Observations of rotational velocities in disk galaxies indicate that the bulk of the mass of these objects is invisible 'dark matter'. Moreover, this dark matter is distributed so that the rotational velocities of stars, H II regions and neutral hydrogen 14-18 are approximately independent of radius out to distances near to and even well beyond the optical radius of the galaxy. This implies a density (ρ) of dark material that, at large radii, falls off like;

$$\rho(r) \sim r^{-2} \tag{2}$$

or alternatively, the mass profile:

$$M(r) \sim r \tag{3}$$

We will demonstrate that mass profiles of this kind can be obtained when the initial density perturbations have at least as much energy on the large scale as they have on the small scale,

n < -1. This conclusion has been anticipated analytically by the 'secondary infall' models proposed by Gunn and Gott¹⁹. In particular, using the secondary infall paradigm, Hosimann and Shaham²⁰ have conjectured that the average density profile should be related to the power-law exponent n by

$$\rho(r) \sim r^{-\gamma} \tag{4}$$

where

$$\gamma = \frac{3(3+n)}{(4+n)} \tag{5}$$

for n>-1, and should relax to $p\sim r^{-2}$ for -1>n>-3. Our results are in approximate agreement with these conclusions for n>-2, even though the process of formation of collapsed objects does not seem to conform with the secondary infall picture.

Computer simulations

A gaussian field of initial density perturbations can be reproduced by writing:

$$\Delta \rho(\vec{r}) = \rho(\vec{r}) - \langle \rho \rangle$$

$$= \sum_{\vec{k}} |\delta_{\vec{k}}| e^{-i\phi_{\vec{k}}} e^{-i\vec{k}\cdot\vec{r}}$$
(6)

Here $|\delta_{\vec{k}}|$ are the absolute values of the complex amplitudes of all the modes and $\phi_{\vec{k}}$ are their phases. One can realize power spectrum $P(\vec{k})$ by choosing:

$$\delta_{\vec{k}} = \sqrt{2P(\vec{k})} R_{\vec{k}}^{\delta} \tag{7a}$$

$$\phi_{\mathcal{E}} = 2\pi R_{\mathcal{E}}^{\phi} \tag{7b}$$

where $\{R_{\vec{k}}^{\delta}, R_{\vec{k}}^{\phi}\}$ are a pair of random numbers with distributions which are, respectively, gaussian in the interval $(0, \infty)$, and uniform in the interval (0, 1].

We have found it extremely useful to implement different power spectra by using the same set of random number pairs. This allows us to model 'the same' fragment of the universe with different power laws and therefore to bring out systematic changes which would otherwise be overwhelmed by the random nature of the initial perturbations.

The density distribution can be faithfully represented in the form given by equation (6) only when, on the scales of interest, the amplitude $\sigma = \sqrt{\langle (\Delta \rho)^2 \rangle}$ is much smaller than the average density;

$$\sigma \ll \langle \rho \rangle$$
 (8)

This follows not just from the trivial requirement that ρ be positive; beyond the linear regime mode-mode interactions induce correlations between modes which in turn invalidates

† Theoretical Astrophysics, California Institute of Technology, Pasadena, California 91125, USA
‡ Theoretical Astrophysics, Los Alamos National Laboratory, Los Alamos, New Mexico 87545,

the assumption of gaussian density perturbations and makes the use of equation (6) impossible (see ref. 1).

We guarantee the validity of equation (6) by adjusting the normalization constant A in equation (1) so that mass fluctuations on the scale-of-interest (Λ) are small:

$$\left[\frac{\delta M}{M}\right]_{\Lambda} = 0.06\tag{9}$$

We impose the same condition on $\delta M/M$ for the CDM models. It will be useful but will entail no loss of generality, to refer to this chosen scale A by analogy with the CDM case—for which A can be estimated by comparison with present-day galaxy correlation functions 12,13,21—as the 'megaparsec scale'. In other words, we anticipate that 'galactic haloes' will form from Λ-sized fragments of the initial distribution after a time interval corresponding to the Hubble time. With this convention in mind we can now state that our models are initiated with the Hubble constant $H_o = 100 \text{ km s}^{-1} \text{ M pc}^{-1}$ at $z_{\text{int}} = 24$ and are evolved for ~10,000-14,000 Myr beyond the conventional present which for this set of initial conditions occurs at an unrealistically short time of 6,700 Myr after the big bang. It is essential to keep in mind that for the power law models the above convention is nothing but a convention as the scale-free nature of $P(\vec{k})$ implies. Our results—density profiles of haloes—are independent of the value of H_0 . The Hubble constant influences only the total values of the masses of haloes, but not their shapes.

The initial conditions are imprinted on a system of 64^3 particles, each of them with a conventional mass of $m = 1.02 \times 10^9 M_{\odot}$, $\Omega = 1$. They represent a $(10 \text{Mpc})^3$ section of the model universe. The initial conditions are imposed using the Zel'dovich 'growing mode' method^{1,20,22} which deforms the cubic lattice of particles in the desired manner. The evolution of the system to z = 0 is then simulated by a Fourier (cloud-in-cell) code with a 64^3 mesh.

The Fourier methods are inaccurate on scales smaller than a few mesh spacings. Therefore, we use it only to set up initial conditions for the N-body simulations. These are provided by the output of the Fourier code at z=5.25 and/or z=10.1. (We do not want to generate initial conditions this late in the history of the universe, as by then the inequality (8) is no longer valid and equation (6) cannot be trusted.) The use of the Fourier code allows us to employ sufficiently many particles at very early times to imprint initial conditions without the danger of introducing errors via shot noise or aliasing (ref. 21 and work in preparation). Moreover, using this technique we can obtain the first 'blurred' but, nevertheless, informative pictures of the model at z=0.

Two kinds of N-body runs are used. Low-resolution simulations use particles with a mass $M_L = 27 \,\mathrm{m}$. A sphere with a diameter of 10 Mpc cut out from the Fourier cube provides the initial conditions. Each of the low resolution particles has the location and the velocity of the centre of mass of a $3 \times 3 \times 3$ fragment of the original Fourier lattice. However, particle masses are now close to $3 \times 10^{10} \,\mathrm{M}_\odot$ which means that a typical galactic halo will contain no more than ~100 particles. Therefore, to investigate smaller scale structures we have employed a different mapping of the Fourier particles onto the N-body initial conditions.

High-resolution runs use a one-to-one mapping in a chosen sphere of 2 Mpc radius, and a very low-resolution mapping (64 Fourier particles to one N-body particle) towards the outskirts of the model. Masses in the transition region between 2 and 3 Mpc take on intermediate values. The resulting multi-resolution system is evolved using the N-body code for a time comparable to the corresponding low-resolution run (see Fig. 1).

Typically 5,000-7,000 particles are evolved and a run is completed within 2-4 hrs of Cray-1 CPU time. Usually more than one high-resolution sphere-of-interest is chosen for each low-resolution model. Therefore, the same fragment of the universe is modelled using three distinct resolutions. All of the N-body runs use a smoothing length of 10 kpc. Note that on the scales

on which all three resolutions are expected to be accurate, all of them yield comparable results. Low-resolution runs are then used to extract information about the large-scale structure, mergers, and so on. The results of these runs will be discussed elsewhere. Here we shall concentrate on the small-scale information contained in the high-resolution runs. Specifically, we shall consider the density profiles of haloes, that is objects with masses between $10^{11} M_{\odot}$ and $10^{12} M_{\odot}$.

Halo density profiles

Figure 2 contains a graphic summary of the key results discussed in this section. Two conclusions are immediately apparent: (1) the high-resolution portions of the particle plots in Fig. 2 contain related structures (the 'same' halo can be usually identified in the figures corresponding to the neighbouring values of n). (2) The realizations with more power on small scales (larger n) have larger numbers of more compact haloes. In particular, while the model with n=-2.75 exhibits only two reasonably well developed haloes, there are about 10 such structures of various sizes for n=1. Moreover, models with a lot of power on the large scale exhibit more pronounced 'caustics' and 'filaments'. The CDM model is the closest in appearance to the n=-1 and n=-2 cases. This is not unexpected: the effective exponent of the cold dark matter power spectrum is close to -1.5 on the megaparsec scale.

Most of the haloes in the high resolution region contain only high-resolution particles. However, some of them are contaminated by heavy particles that have entered from the low-resolution part of the model. The results given below are inferred from haloes that contain ≤10% of these heavies by mass. (In fact, only 10% of the analysed halos had more than 1 or 2 heavies).

For the densities given by equation (4), the mass profile (the mass within radius r) is given by the relation:

$$M(r) \sim r^{3-\gamma} \tag{10}$$

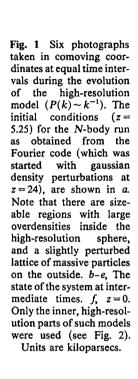

The corresponding rotational velocity inferred for such M(r) is;

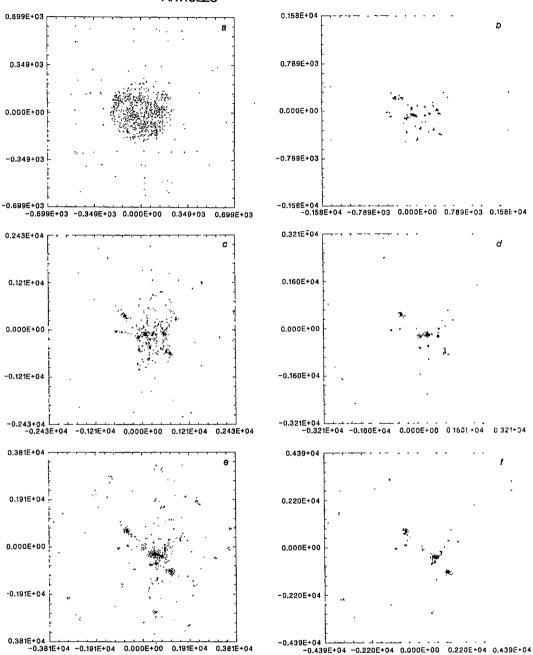

$$v(r) \sim r^{(2-\gamma)/2} \tag{11}$$

The circular rotational velocities of haloes obtained in the computer experiment are for a subset of the haloes shown in Fig. 2. We also indicate there the velocity profile predicted by equation (5).

Models with n=1 and n=0 produce centrally condensed haloes with the mass falling off faster than in the flat rotation case. The typical slope of the density profile is well approximated by the value of γ inferred from equation (5) although a systematic discrepancy can also be noted: densities tend to fall off faster than equation (5) would have it. In particular, rotation curves are not quite flat for n=-1 but clearly flatten for CDM as well as for the n=-2 case. In all cases when n>-1 rotation curves flatten at radii between 10 and 20 kpc. (The resolution of our N-body code is 10 kpc and does not allow us to comment on the structure on the innermost parts of the halo.) It is interesting that virtually all haloes formed in a simulation with a given power law have very similar rotation curves.

The situation is different when n = -2.75. Now the rotational velocities are still rising at r = 50 kpc and some of them do not flatten even in the 100 kpc range. This seems to imply that the structure of these haloes is inconsistent with the conclusions of Hoffman and Shaham, who conjecture that flat rotation curves will form even for n = -3. It is unlikely that such haloes with rising rotation velocities are a temporary, unstable phenomenon: We have checked the slope of the density profile at z = -0.5, at a time equal to 14,000 Myr. It is still rising and equation (5) still provides as good an estimate as a flat rotation profile. More relevant in understanding this discrepancy is probably the systematic increase of the size of the soft core with n decreasing to -3. This trend is visible already for n = -2. Indeed, rotation profiles between 100 and 200 kpc, not shown in Fig. 2, are quite

flat for n = -2.75. Therefore, the relevant part of Fig. 2 may be showing just the soft core parts of the haloes for this case. Moreover, the treatment given in ref. 20 breaks down for n < -3. Hence, it is not too surprising that its predictions for n = -2.75 are inaccurate. Indeed, one should be surprised that the arguments of Hoffman and Shaham give as good an estimate of the resulting density profiles as they do, as the assumptions on which they are based are only approximately valid.

The mass profile of the cold dark matter haloes is reasonably close to the flat rotation curve variety out to 100-150 kpc. Beyond that distance rotation profiles begin to fall off. The rotation parameters (λ) of the collapsed objects are typically in the 0.05-0.1 range ($\lambda = |E|^{1/2}J/GM^{5/2}$, where E is the total energy of the halo, J its angular momentum, M its mass, and G is the gravitational constant.) This is consistent with our earlier findings^{24,25} as well as with a number of other cold dark matter simulations²⁶.

We have concluded that the mass profiles of collapsed, virialized objects in the $\Omega=1$ universe initiated with an effective power law spectrum on the galactic scale are determined over the range of interest by the value of n. Equations (4) and (5)

give a fair estimate of the corresponding density profiles. Although a power spectrum translates unambiguously into a rotation curve, one should keep in mind that the reverse argument is not so straightforward: The fact that a flat rotation curve is observed, often allows, within the errors, a range of halo density profiles. Moreover, baryonic material in the dissipative process of settling in the centre of the core will inevitably steepen the final rotation curve²⁷.

Comparisons with theory

Gunn and Gott have developed the secondary infall scenario based on the assumption that the formation of collapsed objects in an overdense region begins from the density peak which in due course accretes surrounding shells of material ¹⁹ Each of these shells is thought to be much less massive than the already collapsed and virialized core. Assuming spherical symmetry, one can show that material from each consecutive shell will be eventually deposited at a radius:

$$r = \frac{r_{\rm m}(\beta - 1)}{2} \tag{12}$$

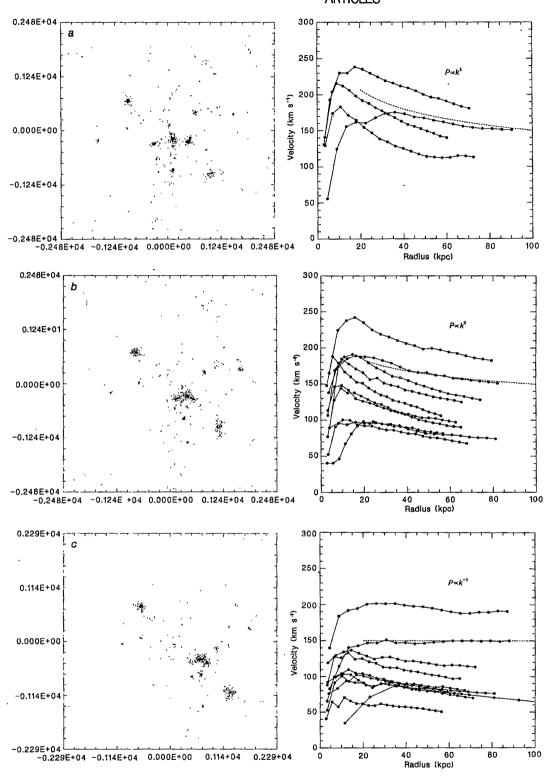

Fig. 2 The formation of haloes in an EinsteindeSitter $(\Omega = 1)$ universe different power spectra. Particle plots show only the inner, highresolution regions. The exponent of the power law is indicated in the plots of the rotation velocities. The rotation profile predicted by $\rho(r) \sim r^{-3(3+n)/(4+n)}$ is indicated by dashed line. A scaled down average rotation profile of Sc spirals, ref. 15, is plotted along with the CDM haloes.

around the centre, where $r_{\rm m}$ is the radius of maximum expansion, and β characterizes the density of the already virialized core:

$$\rho(r) \sim r^{-\beta} \tag{13}$$

With a few additional assumptions, this can be used to calculate the density profile. The maximum radius of expansion for a spherically symmetric density perturbation with the initial relative overdensity δ_i is given by:

$$r_{\rm m} = r_{\rm i} \frac{1 + \delta_{\rm i}(r_{\rm i})}{\delta_{\rm i}(r_{\rm i}) - (\Omega_{\rm i}^{-1} - 1)}$$
 (14)

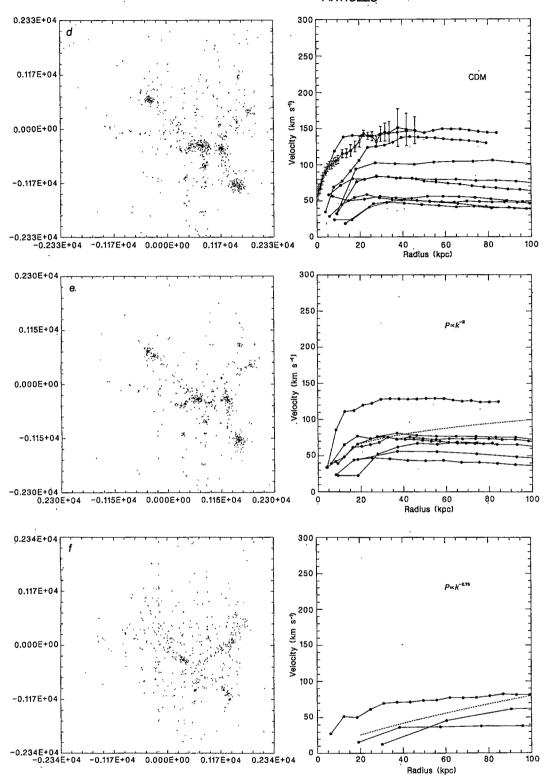

Here δ_i characterizes the initial overdensity inside the sphere of radius r_i :

$$M(r < r_i) = \left(\frac{4\pi}{3}\right) r_i^3 \langle \rho \rangle (1 + \delta_i(r_i)) \tag{15}$$

In the case considered here $\Omega_i = 1$. Therefore, the final density of the halo is:

$$\rho(r) \sim \delta_{\rm i}(r_{\rm i}(r))^3 \tag{16}$$

Hoffman and Shaham²⁰, following Peebles¹², argue that in a universe with a scale-free spectrum of initial density perturba-

tions, given by equation (1), the relative overdensity around a local maximum can be estimated by:

$$\delta_{i} \sim \left(\frac{r_{i}}{r_{\lambda}}\right)^{-(3+n)} \tag{17}$$

Here r_{λ} is the characteristic smoothing distance ^{12,20,28}, related to the distance between the peaks. Consequently, the final density of the collapsed halo is given by:

$$\rho(r) \sim (r_i(r))^{-3(3+n)} \tag{18}$$

To express the right-hand side of this relation in terms of the distance from the halo centre we use equation (14) together with equation (17) to obtain:

$$=\frac{r_{\rm m}(\beta-1)}{2}$$

$$\sim \frac{(\beta - 1)}{2} \left(\frac{r_{\rm i}}{r_{\rm i}}\right)^{4+n} \tag{19}$$

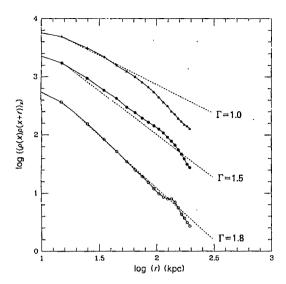

Fig. 3 Density autocorrelation functions, equation (21), for the particles in the high-resolution portions of some of the power law models. The prediction of the hierarchical clustering scenariopower law with the exponent given by equation (22)—is indicated by the dashed line. Results for: \triangle , n = -2; \bigcirc , n = -1; \bigcirc , n = 0respectively. Note that each curve has been offset vertically by an arbitrary amount for clarity.

Therefore.

$$\rho(r) \sim \left(\frac{r}{r_{\lambda}}\right)^{-3(3+n)/(4+n)} \tag{20}$$

Our derivation of equation (20) paraphrases a more detailed discussion in ref. 20.

Hoffman and Shaham, following Fillmore and Goldreich²⁹, conjecture that the mass profiles with $M \sim r^{1+\epsilon}$, $\epsilon > 0$, are unstable. Therefore, they conclude that haloes with $\gamma < 2$ will relax into flat rotation curve haloes. This additional conjecture has not been so far confirmed by our computer models. The key difference between the situation analysed by Fillmore and Goldreich and our computer simulations may be due to the absence of angular momentum in the spherically symmetric, self-similar calculations reported in the ref. 29. Large angular momenta may stabilize haloes with rising rotation curves.

The analysis leading to equation (20) hinges on assumptions which are at best only approximately valid: (1) The initial overdensity profile, equation (17), is a reasonable estimate of the actual density profile only for a limited range of initial radii. When $r < r_{\lambda}$, near the peak, $\delta_i(r_i)$ is flatter than equation (17) would suggest. Moreover, for larger r, fluctuations of overdensity soon begin to exceed the systematic behaviour given by equation (17)^{20,28}. Therefore, the derivation is based on an assumption which is approximately accurate only for a rather limited range of radii. (2) A detailed discussion by Bardeen et al.28 shows that the criterion implicitely used by Hoffman and Shaham to define density maxima is biased towards unusually broad peaks. (3) The density profile around correctly chosen density maxima falls off more steeply than equation (17) would have it. This difference may account for the discrepancy between the rotation curves predicted on the basis of equation (20) and the steeper rotation profiles obtained in our simulations. (4) The paradigm of the secondary infall onto a peak does not appear to be valid in the course of collapse leading to the formation of the haloes considered here. In particular, merging of smaller, already collapsed objects (see Fig. 1) appears to be a better description of the formation process. This is at odds with the picture of shells deposited spherically symmetrically onto a pre-existing core. In

spite of all these problems equations (4) and (5) give a reasonably accurate prediction of the density profiles of the collapsed objects. Discrepancies, which we have already pointed out in the previous section, are worth further study.

Scale-free spectra lead to a self-similar clustering hierarchy⁵⁻¹⁰ Peebles has pointed out that the density autocorrelation function in an evolved region of such a hierarchical universe should have a power law form⁶:

$$\langle \rho(x)\rho(x+r)\rangle_x = r^{-\Gamma}$$
 (21)

with an 'hierarchical' exponent Γ given by:

$$\Gamma = \frac{3(3+n)}{(5+n)} \tag{22}$$

This Γ differs from the γ in the density formula, equation (5). We have verified (see Fig. 3) that this estimate for Γ is indeed correct in the high-resolution portions of our models. Note, perhaps not unexpectedly, that when the density autocorrelation is calculated only for the particles inside the haloes—that is, for x chosen from within the perimeter of the halo, but for an arbitrary r in the notation of equation (21)—it is considerably steeper, with the effective power law exponent close to the one given by equation (5).

Conclusions

Our numerical experiments provide clear evidence of a direct connection between the form of the power spectrum responsible for the gaussian density perturbations and the rotation curves of the resulting haloes. In particular, $P(k) \sim k^n$ with $n \sim -1 \rightarrow -2$ leads to flat rotation curves in present day galactic haloes. Power law spectra with n > -1 give haloes with rotation curves steeper than observed. This puts severe constraints on the shape of the power spectrum in the range corresponding to 1 Mpc. Furthermore, baryon condensation in the central parts of the halo can be expected to further steepen the rotation profile²⁷. This indicates that density perturbations with the preponderance of the power on small scales are untenable as models for galaxy formation. On the other hand, baryon condensation can probably flatten rising rotation curves inside broad soft cores, making n = -1 or n = -2 attractive. The cold dark matter power spectrum falls into the category of spectra producing haloes compatible with observations. Further studies to determine the environment dependence of other halo properties (such as the radii of their soft cores, angular momenta, and eccentricities) are underway.

We thank Stirling Colgate, Richard Epstein, Mike Fall, Yehuda Hoffman, Craig Hogan, Robert Hotchkiss, Nick Kaiser, Jeremy Ostriker and Martin Rees for stimulating discussion and help. Completion of this project would have been impossible without the large amounts of computer time provided by Los Alamos National Laboratory, Caltech and the Space Telescope Science Institute. We thank Kate Quinn for helping to prepare the manuscript.

The cytoplasmic carboxy terminus of M13 procoat is required for the membrane insertion of its central domain

Andreas Kuhn, William Wickner & Günther Kreil

Molecular Biology Institute and Department of Biological Chemistry, University of California, Los Angeles, California 90024, USA

The M13 coat protein spans the Escherichia coli plasma membrane with its amino-terminus facing the periplasm. It is made as a precursor—the procoat—with a typical leader peptide. Mutations which destroy the basic character of the carboxy-terminal domain of procoat, a domain which is oriented towards the cytoplasm, block membrane assembly, while insertion of three lysyl residues near the carboxy terminus partially restores assembly. Thus the information specifying membrane insertion of M13 procoat protein is found in its mature region as well as the leader and is not simply decoded in an amino to carboxy direction.

MANY secreted and membrane proteins are made with basic, amphiphilic leader (signal) peptides of 15 to 30 residues at their amino-terminus¹⁻³. Leader peptides are removed by an endoprotease, the leader peptidase⁴, after the pre-protein has crossed the membrane. Although leader peptides are essential for the processes of secretion and membrane assembly⁵, their precise roles have been the subject of speculation (reviewed in ref. 6) and are not yet established. Careful compilation and analysis^{2,3} have shown that certain features, such as the distribution of charged and apolar residues, are common among leader peptides. In contrast, there is no apparent sequence conservation among the mature regions of secreted proteins or extracytoplasmic domains of transmembrane proteins. This has led to the concept that the information specifying protein translocation into, or across, a membrane lies solely in leader peptides⁷.

Mutations in bacterial proteins which impair their export to the plasma membrane, periplasm or outer membrane can define domains which are relevant to this process. Almost all available mutations which affect the translocation of the λ receptor or the maltose-binding protein are in the leader region⁸. Furthermore, deletion of the carboxy-terminal regions of β -lactamase⁹ or maltose-binding protein¹⁰ has no effect on their export. These studies supported the concept that the leader peptide is sufficient to specify translocation.

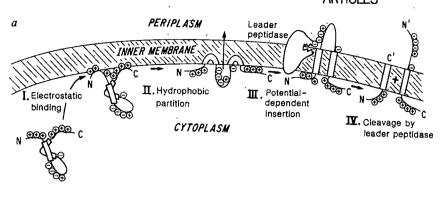

However, other studies have implicated the mature region of pre-proteins in membrane transit processes. In bacteria, protein translocation is a late or post-translational event¹¹⁻¹³, suggesting that the carboxy-terminus may have a necessary role. Indeed, fusion proteins comprised of the leader peptide of a secreted protein and the carboxy-terminal region of a cytoplasmic protein cannot cross the plasma membrane 14,15. Furthermore, Silhavy and colleagues 16 have shown that over half of the 'mature' region of the λ receptor must be present in a fusion protein to permit export. The relative roles of the leader and mature domains of a pre-protein during its export across the plasma membrane of Escherichia coli have thus remained undefined.

Membrane assembly of procoat

We have studied the biosynthesis of M13 coat protein, a small protein (relative molecular mass (M_r) 5,280) which spans the inner membrane of M13-infected cells¹⁷. It is made as a precursor, termed procoat $(M_r, 7,628)$, with a 23-residue leader peptide (Fig. 1). Our working model of procoat membrane assembly is shown in Fig. 1a. Procoat has two hydrophobic domains (drawn as rectangles in Fig. 1), one in the leader and one which spans the membrane in mature coat protein. Its membrane insertion is not coupled to either secA or secY function 18 or to polypeptide synthesis¹⁹, but does require the transmembrane electrochemical potential²⁰. Transmembrane procoat is cleaved by leader peptidase to yield coat protein and the leader peptide, which is rapidly degraded. The biosynthesis of this protein has been studied extensively, both in vivo and in crude and reconstituted in vitro reactions^{21,22}. However, only a few mutants of this protein have been described.

In a recent study, we cloned the procoat gene and used in vitro mutagenesis with hydroxylamine to create mutations²³. More than 40 mutants were identified, of which 3 were in the leader sequence near the leader peptidase cleavage site²⁴. These three mutations affected the cleavage of procoat by leader peptidase, yet did not prevent procoat insertion across the membrane. In fact, despite careful screening, no mutations were identified which blocked membrane insertion. Examination of the 111 transitions which hydroxylamine could potentially cause in this gene of 219 base pairs (bp) revealed that only 68 would lead to amino-acid substitutions, and most of these would be quite conservative. Current mutagens only yield a very limited variety of mutants. Thus the failure to create export-defective mutations in the mature domain of secretory and membrane proteins, with currently available mutagens cannot be taken as evidence that such mutations cannot occur.

In the present study, we have circumvented this problem by directly altering the carboxy-terminus of procoat with recom-

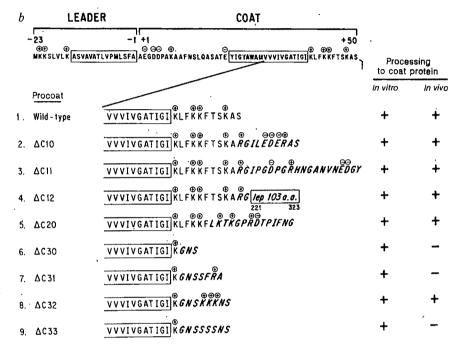

Fig. 1 a, A working model for the membrane insertion of M13 procoat. b, Construction of procoat mutants.

Methods. The procoat gene was cloned into the pING-1 vector²³ and excised by digestion with Sall and EcoRI. It was purified by electrophoresis in 0.7% agarose and then partially cleaved with AluI. This restriction endonuclease can cleave the procoat gene after the second base of the codon of the COOHterminal serine and after the codon for lysine +40. The partially digested procoat gene was inserted into the pING plasmid which had previously been digested with SalI and SmaI. This yielded plasmids Δ C10 and Δ C30, respectively. As a second step, the plasmid $\Delta C10$ was cut with EcoRI and ligated with the EcoRI fragment of leader peptidase. This contains the codons for the COOH-terminal region of leader peptidase, starting at isoleucine 221 and extending 52 bp beyond the stop codon. The resulting plasmids $\Delta C11$ and $\Delta C12$ contained this fragment in the opposite and same orientations as the leader peptidase gene, respectively. In ΔC12, the reading frame of the leader peptidase gene is retained, yielding a fusion protein. The same EcoRI fragment was also inserted into the plasmid $\Delta C30$. This yielded only one phenotype, represented by plasmid ΔC31. Finally, the two complementary oligonucleod(AATTCGAAGAAGAAG) d(AATTCTTCTTCTG) were synthesized and ligated into plasmid AC30 which had been digested with EcoRI. Depending on the orientation, this resulted in the insertion of three lysine (Δ C32) or three serine (Δ C33) residues. During screening for the clones Δ C11 and Δ C12, a new phenotype was observed which corresponded neither to the parent plasmid Δ C10 nor to Δ C12. This plasmid, termed $\Delta C20$, was shown by sequencing to have a deletion which alters the amino-acid sequence of procoat after residue

+45.

binant DNA techniques, including oligonucleotide-directed mutagenesis. We find that the basic character of the carboxy terminus of procoat is as essential for its membrane assembly as the leader peptide.

Carboxy-terminal mutations

The sequence of wild-type M13 procoat, and of mutations which we have created near the carboxy-terminus, are listed in Fig. 1b. The mutants are designated 'AC' to indicate the deletion of procoat near the carboxy terminus. The first digit after the C indicates which restriction site was used for the construction, while the second simply lists the various derivatives made at that site. All the AC constructions migrated at their expected M_r on SDS-polyacrylamide gel electrophoresis. Each was readily cleaved to its mature size in cell-free detergent extracts, as expected for the known substrate specificity of leader peptidase (ref. 25 and Figs 2, 4). We have shown previously that such cleavage is at the amino terminus, and is due to leader peptidase²⁴. In addition, the in vitro conversion of procoat to coat was shown to be inhibited by purified leader peptide (data not shown). Since these mutant procoat proteins are substrates for leader peptidase, their processing in vivo is an accurate indicator of whether they have assembled across the plasma

Procoat mutants Δ C10, Δ C11 and Δ C12 retained all but the carboxy-terminal serine of procoat, while adding 10, 20 or 105 polar amino-acid residues. Each of these mutant procoats rapidly chased to its respective mature form, though some of the precursor was lost to cytoplasmic degradation (Fig. 3, lanes

1, 2; 7, 8; 9, 10; odd-numbered lanes are pulse-labelled; evennumbered lanes are chased for 60 s). Since it has been suggested that the assembly properties of procoat are a function of its small size, we characterized the largest of these mutants, Δ C12, in detail. To create this mutant, a restriction fragment encoding the carboxy-terminal 103 polar amino-acid residues of leader peptidase was joined (in-frame) to the 3' end of the procoat gene. Its membrane assembly and orientation are indicated diagrammatically in Fig. 4a. In vitro, Δ C12 is synthesized as a precursor (Fig. 4b, lane 1) which can be cleaved to its mature M, by leader peptidase (Fig. 4b, lane 2). In vivo, even a brief pulse-label reveals largely mature $\Delta C12$ (Fig. 3, lane 9, and Fig. 4c) and only a small amount of precursor. This presumably simply reflects membrane assembly during the additional time needed to synthesize the 103 extra carboxy-terminal residues. Correct assembly was confirmed by protease mapping (Fig. 4c). Cells. synthesizing $\Delta C12$ were pulse-labelled with methionine, then chilled and treated with Tris, sucrose and EDTA to permeabilize the outer membrane. These cells, or cells lysed with detergent, were digested with proteinase K for the indicated times. Aliquots were immunoprecipitated with antiserum to coat protein or to leader peptidase and analysed by SDS-polyacrylamide gel electrophoresis (PAGE) and fluorography. Although a small fraction of the cells lysed during the experiment, the precursor form of $\Delta C12$ was largely inaccessible to protease, though it was completely degraded when the cells were lysed with detergent. The mature form of Δ C12 was cleaved to a form of sightly lower M_r by proteinase K added to intact spheroplasts. This lower M_r form retained the carboxy-terminal

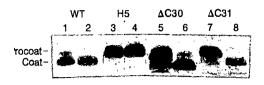

Fig. 2 Sensitivity of wild-type and mutant procoats to digestion by leader peptidase in detergent mixed micelles. E. coli HJM114bearing plasmids with either the wild-type or various mutant procoat genes (as noted) were grown at 37°C in minimal medium 9 (ref. 32) containing 0.5% fructose and a supplement of the mixed amino acids, less methionine. At an absorbance at 600 nm of 0.05, arabinose was added to 0.5% and growth continued for 2 h. Each culture (1 ml) was then labelled for 30 s with 50 µCi 35S-methionine (1,000 Ci mmol⁻¹). Cultures were added to 0.25 ml of 30% sucrose, 0.6 mg ml^{-1} lysozyme, 0.03 M EDTA, 3% (v/v) Triton X-100, and 100 µg ml⁻¹ DNase I. Each sample was frozen in a dry ice/ethanol bath, then thawed and incubated for 30 min at 0 °C. Aliquots (0.2 ml) were either held on ice (lanes 1, 3, 5, 7) or incubated at 37 °C (lanes 2, 4, 6, 8) for 1 h, then analysed for procoat and coat by immunoprecipitation, SDS-PAGE and fluorography. Procoat H5 is a mutant in the leader peptidase target site of procoat²⁴.

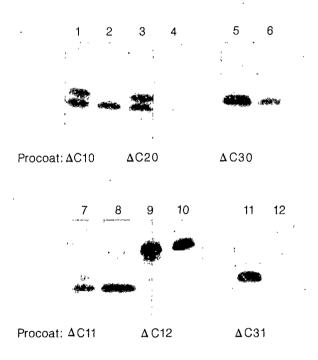

Fig. 3 Phenotypes of ΔC mutant procoats. Recombinant plasmids were transformed into wild-type E. coli HJM114. Cultures were grown overnight at 37 °C in M9 minimal medium containing ampicillin and glucose. Fresh overnight cultures were diluted 1:100 into M9 minimal medium containing 0.5% arabinose and grown at 37 °C to a density of 3×10^8 cells per ml. Aliquots were pulselabelled for 30 s with $10~\mu Ci$ of $^{35} S$ -methionine, then chased for either 5 s (odd-numbered lanes) or 60 s (even-numbered lanes) in the presence of unlabelled methionine. Samples were precipitated with trichloroacetic acid and analysed by immunoprecipitation, SDS-PAGE and fluorography.

leader peptidase immunological determinants, but was no longer immunoprecipitable by antiserum to coat protein (Fig. 4c). Δ C12 therefore has the expected orientation across the plasma membrane, with its amino terminus facing the periplasm and its carboxy terminus exposed to the cytoplasm. Mutants Δ C10 to Δ C12 demonstrate that simply elongating the carboxy terminus of procoat does not interfere with membrane assembly.

Procoat Δ C20 has lost the original carboxy-terminal 5 residues of procoat, including lysine +48, and in their place has sub-

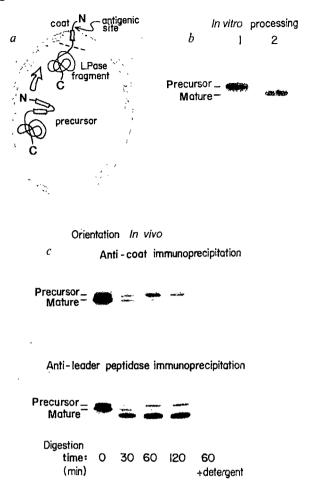

Fig. 4 Procoat Δ C12 is translocated across the membrane and processed. a, Schematic representation of the cellular localization of procoat Δ C12 and coat Δ C12. b, Plasmid-directed synthesis of procoat Δ C12 in vitro and its cleavage to a mature form by purified leader peptidase. c, Protease-accessibility of procoat and coat Δ C12.

Methods. Purified plasmid DNA encoding procoat ΔC12 was added to cellular extracts (S-30) of E. coli HJM114 in the presence of 0.4% arabinose, 0.5% Triton X-100 and purified ara C protein (200 μg ml⁻¹; a gift from Dr G. Wilcox, Ingene Inc.). Incubation was at 37 °C for 1 h under the conditions described by Zalkin et al.³³ either in the absence (lane 1) or in the presence (lane 2) of 50 μg ml⁻¹ purified leader peptidase⁴. For c, exponentially growing cells were pulse-labelled with ³⁵S-methionine for 1 min and osmotically shocked by mixing with an equal volume of ice-cold 60 mM Tris-HCl, pH 8.0, 40% sucrose, 20 mM EDTA. These cells were incubated with proteinase K (1 mg ml⁻¹) for the indicated times without (lanes 1-4) or with (lane 5) 2.5% Triton X-100. The samples were then immunoprecipitated with antibodies to coat (upper panel) or to leader peptidase (lower panel) and analysed by SDS-PAGE and fluorography.

stituted 14 polar, basic residues. It also assembles across the plasma membrane and is processed to coat protein (Fig. 3, lane 3), though this assembly reaction is inefficient. Δ C20 procoat was inaccessible to added proteinase K in spheroplasts, while the mature Δ C20 was degraded (Fig. 5a), confirming that processing reflected membrane assembly. Both the precursor and mature forms of Δ C20 were rapidly degraded in vivo (Fig. 3, lane 4). The precursor form is far more stable in a htp, lon strain (Fig. 6b), which lacks the cytoplasmic, ATP-dependent lon protease²⁶, indicating that procoat Δ C20 is normally degraded by the cytoplasmic lon protease in wild-type cells. The mature form of Δ C20 is still degraded, presumably by a different proteinase.

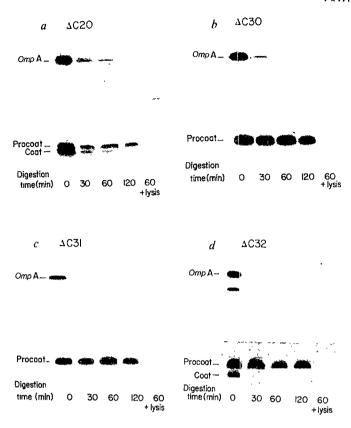

Fig. 5 Protease-accessibility to test for insertion of procoat into the membrane. Exponentially growing cultures of LC 137 which bore plasmids coding for procoat Δ C20 (a), Δ C30 (b), Δ C31 (c), or Δ C32 (d) were pulse-labelled with ³⁵S-methionine for 1 min, chased with an excess of L-methionine for 1 min, and osmotically shocked by thorough mixing with an equal volume of ice-cold 60 mM Tris-HCl pH 8.0, 40% sucrose, and 20 mM EDTA. Proteinase K (Boehringer) was added to a final concentration of 1 mg ml⁻¹ and incubated at 0 °C for the indicated times. For some samples, the cells were lysed by addition of 2.5% Triton X-100. Proteinase K was inactivated by addition of phenylmethanesulphonyl fluoride (Sigma) and 20% trichloroacetic acid. The acid precipitates were collected by centrifugation, twice resuspended in ice-cold acetone, sedimented and resuspended in 50 µl of 10 mM Tris-HCl (pH 8), 2% SDS and incubated for 5 min at 95 °C. Each sample was then diluted with 1 ml of 2% Triton X-100, 0.1 mM EDTA, 0.15 M NaCl, 10 mM Tris-HCl pH 8.0 (buffer A) and mixed with 15 µl of a 10% suspension of formalin-fixed, SDS-washed Staphylococcus aureus¹¹ for 30 min. The S. aureus cells were removed by centrifugation. Antiserum to M13 coat protein and the outer membrane protein (Omp A) was added to the supernatant and incubated overnight. After addition of 15 µl of a 10% suspension of S. aureus cells, the samples were incubated for 1 h and centrifuged. The cells were sequentially suspended in buffer A and buffer A minus detergent and collected by centrifugation. They were then mixed with electrophoresis sample buffer, boiled and applied to 19% polyacrylamide gels in SDS containing 6 M urea. After electrophoresis, the gels were fixed, incubated in salicylate, dried and fluorographed11.

Altering the carboxy terminus

In the mutant Δ C30, the carboxy-terminal 10 residues of procoat were replaced by the sequence Gly-Asn-Ser. This yields a precursor which contains 66 rather than 73 residues and which lacks 3 of the 4 lysyl residues present in the cytoplasmic 'tail' of the wild-type protein. Surprisingly, this change at the carboxy terminus of procoat completely prevents its processing (Fig. 3, lanes 5, 6). Since procoat Δ C30 is an excellent substrate for leader peptidase *in vitro*, the absence of *in vivo* processing indicates that it failed to insert across the plasma membrane.

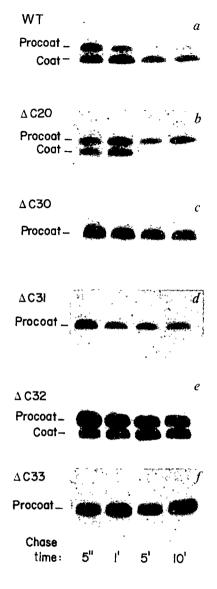

Fig. 6 In vivo processing of procoat mutants. Exponentially growing cultures of E. coli LC 137 (htp⁻, lon⁻) with plasmids coding for wild-type (a) or mutant (b-f) procoat were pulse-labelled with ³⁵S-methionine for 30 s and chased with an excess of L-methionine for the indicated times. Samples were analysed by immunoprecipitation, SDS-PAGE and fluorography.

The mutant precursor is slowly degraded in wild-type cells but not in the htp, lon mutant (Fig. 6c). This provides a second criterion that procoat Δ C30 remains in the cytoplasm. Procoat Δ C30 was also found to be inaccessible to protease in intact spheroplasts (Fig. 5b), confirming that it does not insert across the plasma membrane. These results cannot be explained by any combination of leader, stop-transfer and start-transfer sequences⁷; they are readily explained if procoat Δ C30 fails to form a spontaneous insertion domain⁶.

A derivative of Δ C30 was obtained by inserting the EcoRI fragment of the leader peptidase gene into the EcoRI site of the Δ C30 gene. In either orientation, the fragment has only a short open reading frame, yielding procoat mutants of either 70 or 72 residues. Twelve such clones were investigated by pulse-chase experiments of the type described in Fig. 6, but the observed assembly phenotype was in each case the same as for Δ C30. One such plasmid, Δ C31, was sequenced and shown to encode a procoat mutant of 70 residues. The extra seven residues added after lysine +40 of the wild-type sequence are all hydrophilic and include one arginine. Although this precursor is nearly as

large as wild-type procoat and has two positive charges in its carboxy-terminal region, it still cannot translocate across the plasma membrane. It has the following properties: (1) it can be cleaved by leader peptidase in detergent extracts (Fig. 2, lanes 7, 8), but is not processed in vivo (Fig. 3, lane 11); (2) it is rapidly degraded in wild-type cells (Fig. 3, lane 12) but not in cells which lack the cytoplasmic lon protease (Fig. 6b); and (3) it is inaccessible to added protease in spheroplasts (Fig. 5c). Apparently, restoration of neither size nor overall polarity was sufficient to allow translocation of this mutant procoat.

We therefore devised a test of whether the basic charge at the carboxy terminus of procoat was essential for potein translocation. Two complementary oligonucleotides were synthesized which contained EcoRI linkers at their termini and, depending on the orientation, specified three codons for lysine or for serine. The two oligonucleotides were annealed and cloned into the EcoRI site of Δ C30. The resulting procoat mutants showed different behaviour in pulse/chase experiments. Procoat $\Delta C32$, which has three lysines introduced near its carboxy terminus by the oligonucleotides, can insert into the plasma membrane (Figs 5d, 6e), though at a somewhat lower efficiency than wild-type procoat. In contrast, insertion of the oligonucleotide in the other direction, which created procoat Δ C33 with three added seryl residues, did not restore membrane assembly (Fig. 6f). These results indicate that it is the basic charge in the short carboxyterminal domain of procoat which is essential for its insertion across the membrane.

Conclusions

We have shown that the precise sequence of the carboxy terminus of procoat is not required for membrane assembly, yet its basic character is essential. The signal hypothesis, as originally proposed²⁷ and as modified⁷, postulates a vectorial decoding of linear information contained in 'signal' and 'stoptransfer' sequences of a membrane protein in the amino to carboxy direction. Our results demonstrate that the entire procoat protein has a role in the membrane assembly process. The carboxy terminus of procoat does not resemble a signal or stop-transfer sequence. It is highly polar, while apolar amino acids dominate signal or stop-transfer sequences. Since the carboxy terminus of procoat faces the cytoplasm, our results rule out a linear amino-to-carboxy decoding of this protein's assembly information. We suggest that the entire protein folds in a fashion competent for membrane insertion, as suggested by the membrane trigger hypothesis²⁸. Such a folded structure has recently been termed a spontaneous insertion domain⁶.

The carboxy terminus and leader peptide of procoat are not the only regions which are essential for its membrane assembly. We have also found that the introduction of an arginine at position +30 (the centre of the membrane-spanning domain) in place of the normal valine residue blocks membrane assembly (A.K., G.K. and W.W., manuscript in preparation). Thus the hydrophobic domain +20 to +40 is not only a 'membrane anchor', but is also required to initiate the membrane insertion process.

Our current working model of coat protein biogenesis is presented in Fig. 1a. Procoat may need its basic carboxy terminus in order to bind electrostatically to the membrane acidic lipid head groups. Both apolar domains, that in the leader and the apolar membrane anchor of the mature protein, may participate in partition into the apolar fatty acyl core of the membrane. Insertion of the central, polar domain across the membrane would then be driven by the membrane electrochemical potential, followed by cleavage to yield the mature coat protein. This speculative model may provide a framework for designing future studies.

Other proteins, with different assembly characteristics, may also require information encoded throughout their sequence for insertion across the bacterial plasma membrane. Procoat protein is representative of a class of proteins which do not require the sec-encoded functions for their export 18,29. We have also examined the biosynthesis of leader peptidase, an inner membrane protein which requires at least secA and secY function for its membrane assembly¹⁸. Leader peptidase spans the plasma membrane, with its amino terminus facing the cytoplasm and its carboxy terminus exposed to the periplasm³⁰. A polar, central domain which is carboxy-terminal to the membrane-spanning region is essential for the membrane assembly of leader peptidase (R. Dalbey and W.W., manuscript in preparation). Mutations have also been described in the mature regions of λ receptor¹⁶ and pre-maltose binding protein³¹ which affect their export. These results suggest that, in general, various domains of bacterial proteins in addition to the leader sequence may participate in the process of membrane assembly.

We thank Dr Satoshi Miura for performing the experiment shown in Fig. 6b, Dr Pierre Prentki for help with DNA sequencing and Marilyn Rice and Douglas Geisser for technical assistance. Detection of planetary systems and the search for evidence of life

Bernard F. Burke

Department of Physics, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA

The Solar System is our only example of a planetary system, and the Earth is the only known instance of a planet harbouring life. The formation of planetary systems may occur commonly among stars like the Sun, but whether life arises frequently, rarely, or is a unique event is more problematical. Astrometric techniques capable of detecting major planets (similar to Jupiter, Saturn and Uranus) orbiting nearby stars are currently active ¹⁻⁴, but detection of an Earth-like planet is beyond current techniques. Direct imaging of planetary systems (refs 5, 6; B. M. Oliver, unpublished data) is even more challenging, and current opinion seems to have dismissed the possibility of imaging a planet as small as the Earth. The problem is not an impossible one, however: by combining radioastronomy and optical methods, images of Earth-like planets orbiting nearby stars should be obtainable, and their atmospheres could be studied spectroscopically for evidence of life.

Consider the problem of optically detecting an Earth-like planet in orbit about the nearby G5 star τ Ceti, ~3 pc distant. Except for a numerical factor near unity, the signal-to-noise considerations are the same for both interferometric and filledaperture systems. For a planet of diameter d, albedo η (assuming isotropic scattering), in a circular orbit of radius a at maximum elongation, the ratio of planetary to stellar photon flux (S_p/S_s) is $(\eta/16)$ $(d/a)^2$. The flux from an Earth-like planet with a=1 AU is indeed feeble: $(S_p/S_s) = 1.8 \times 10^{-10}$. More explicitly, the total photon flux of τ Ceti is 8.5×10^9 photons m⁻² s⁻¹, and the scattered planetary flux would be 1.5 photons m⁻² s⁻¹. Thus one must have a stable system that permits long integrations, and the flood of photons from the parent star must be reduced. The general system requirements, for a star at distance D whose flux would be S_0 if it were at distance D_0 , can be specified in terms of the effective collecting area A, the relative gain $G(\theta)$ for the star offset by an angle θ (G=1 at peak response) and signal-to-noise ratio r after integration time t: $A/G = r^2$ $(S_s/S_p)^2 (D/D_0)^2/(tS_0)$. For t = 10 h, $r = 10 \sigma$ (where σ is the standard deviation), and using the parameters for τ Ceti $(S_p/S_s =$ 1.8×10⁻¹⁰, $D = D_0$ and $S_0 = 8.5 \times 10^9$ photons m⁻² s⁻¹), detection of an Earth-like planet requires $(A/G) \approx 10^7$ m². As any system would surely have a finite bandwidth, this must be a lower limit. Collecting area and side-lobe suppression are therefore key considerations.

Radio aperture-synthesis techniques have achieved remarkable success, starting from the earliest Cambridge work^{7,8}, and culminating in the Very Large Array (VLA)9. A study of the relationship between the optical and radio cases 10 indicates that, with the signal-to-noise ratio treated in the shot-noise limit, as noted above, the radio concepts carry over to the optical domain. The ability to perform lengthy integrations (K. I. Kellerman et al., personal communication) recently achieved a theoretical signal-to-noise ratio of 5σ after averaging for 76 h with the VLA) gives interferometry a definite advantage if coherent averaging is possible. It is natural, therefore, to consider extending the method to shorter wavelengths, and the optical case will be considered here, leaving infrared possibilities as a separate exercise. Optical interferometry on the ground is limited by 'seeing' fluctuations, and a space-based system would be free of such troubles. The possibilities for space-borne inteferometry have received attention in the past year or so^{11,12}. The dispersedfringe technique^{13,14} provides a solution of the 'white fringe' problem, and at the same time guarantees that every fringe-

visibility measurement retains information on the spectral distribution. For the present problem, the nearby star can provide a phase reference if the equipment is properly designed, thus providing coherent averaging. We therefore consider an interferometric system in space, having a total collecting area of 10-100 m² (the latter is admittedly ambitious). One can immediately see that the gain, G, must be between -50 and -60 dB. With a more realistic 10% bandwidth, the required gain must therefore be in the range -60 to -70 dB. This immediately rules out any interferometric system having uniformly illuminated apertures, because the side-lobe level would be much too high. The aperture illumination must therefore be tapered (apodized, in optical terminology). A simple example (not necessarily optimum) can be given by assuming a Hanning function taper, that is, one with amplitude proportional to $(1+\cos(\pi r/r_0))/2$. The effective area is halved and the half-power primary beam width is increased, but the side-lobe level is decreased markedly.

If a planet like the Earth were orbiting τ Ceti, its maximum elongation would be 0.28 arcs. For this case, we assume an optical array of Hanning-tapered primary apertures, 1.5 m in diameter. With a desired signal-to-noise ratio of 10σ , a bandwidth that admits 10% of the photons, and an integration time of 10 h, it follows that a mean side-lobe level of $-70 \, dB$ and a collecting area of 10 m² would be needed. This would be achieved by a 10-element array, using only photons of wavelength $\lambda > 5.000$ Å. This assumes, of course, that 'noise side-lobes' generated by optical imperfections are not important. Hence, one must be concerned with the optical quality of the system, and Ruze's theory15 for imperfect antennas applies. If the r.m.s. tolerance of the mirrors is $\lambda/60$ over distances ≥ 1 cm, a demanding but not impossible specification, the 'noise' sidelobes due to irregularities induced in the wavefront will be well below -70 dB, a conclusion consistent with the recent work of Mauron¹⁶. Detection of planets orbiting τ Ceti and other close stars, notably the dozen or so Sun-like stars within 6 pc, should therefore be possible.

We next examine spectrometric possibilities. The Earth's oxygen was almost certainly generated by life, probably by bluegreen algae¹⁷, and a high oxygen abundance in the atmosphere of another planet would be a strong indication that life existed there. Owen¹⁸ proposed looking for the oxygen A-band absorption at 7,600 Å, but he did not discuss how it could be done. He thought that Hartley ozone bands beyond 3,000 Å would be hard to distinguish from the Metropoulos-Beutler bands (3,400-2,600 Å) of sulphur dioxide. With the spectroscopic resolution afforded by the dispersed-fringe correlator, however, this is not the case, provided the signal-to-noise ratio is sufficient. The ozone absorption, being at short wavelength, is easier to detect than the oxygen A-band because the side-lobe level is low. It appears that an integration time of $\sim 100 \,\mathrm{h}$ would give $10 \,\sigma$ detection, and SO₂, if present, could also be seen. Detection of the oxygen A-band is more delicate: the required resolution of 80 Å restricts the available photons, while, for fixed aperture size, the long wavelength dictates a raised side-lobe level. Nevertheless, it appears that an integration time of 100 h would give 10σ detection if the star could be kept within 1 marcs of the second null in the diffraction pattern.

Objections can be raised on several points, but there are ready replies. Scattered light, especially from zodiacal particles, might well be present. The signal level is so extended and weak that no problems arise for a zodiacal belt comparable to that of our Solar System. In reply to the objection that high photon efficiency has been assumed, note that present CCD (charge-couple device) detectors already have high photon efficiency. Read-out noise would be no problem because the background starlight effectively floods the field. Even if no further advances are made in the design of photon detectors, the required increase in integration time will be no more than a factor of two. Starlight scattered within the telescopes must be minimized, but careful optical design, as in a coronagraph, should avoid the problem.

The prospects are sufficiently encouraging to justify more intensive examination of interferometric systems in space. The present example has concentrated on the detection of Earth-like planets with familiar life forms, but in general one might expect that a planet teeming with life is likely to exhibit dramatic departures from chemical equilibrium in its atmosphere 19,20. Encouraging results from a successful instrument of the scale described in this note might well encourage more ambitious systems that might examine the ~50 F, G and K stars within 10 pc (J. C. Tarter, unpublished data). In the present discussion, the detection and study of Earth-like planets has been the principal aim; clearly, major planets could be detected easily and quickly by a similar interferometric system, and manifold opportunities would be opened in many other fields of astrophysical research.

A space telescope for infrared spectroscopy of Earth-like planets

J. R. P. Angel, A. Y. S. Cheng & N. J. Woolf

Steward Observatory, University of Arizona, Tucson, Arizona 85721, USA

Owen has reviewed the potential for detecting life on Earth-like planets of nearby stars, from atmospheric spectra. The presence of oxygen, as revealed, for example, by the 7,600-A absorption band, would be of particular significance. But even the direct detection of a Jupiter-like planet around the nearest star is a formidable task, perhaps just possible with the Hubble Space Telescope^{2,3} or with a Michelson interferometer operating at 40µm wavelength4. Earth-like planets, being fainter and closer in, are still more difficult. Here we show that a space telescope of 16 m diameter, apodized in a new way, could image and measure oxygen in the thermal infrared spectra of earthlike planets up to 4 pc away. Several interesting candidate stars lie within this distance.

Observation of our own Solar System from a distance of 4 pc would reveal the Earth at an angular distance of 0.25 arc s from the Sun, and nearly 10¹⁰ times fainter in visible light. Burke⁵ argues that a multi-element interferometer in space could be capable of optical detection and spectroscopy. As we discuss below, this would require mirrors of extraordinary precision. Figure 1 shows the advantage of observing in the infrared. The Earth's thermal flux (measured in photons) is about 20 times

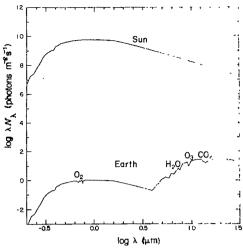

Fig. 1 Fluxes of the Sun and Earth as seen from 4 pc. Detection of spectral features in the photon noise limit depends on the photon flux N_{λ} in a given bandwidth, hence the quantity plotted is $\log(\lambda N_{\lambda})$. The Sun's smoothed flux is from ref. 12. The Earth's optical flux assumes a constant albedo of 0.4 and isotropic emission with the O2 band strengths from ref. 1. The infrared features are an average from ref. 6, normalized to be consistent with re-radiation of 60% of absorbed sunlight.

its optical reflected flux, while the solar flux at 10 µm is 35 times weaker than at 0.7 µm. As photon noise is a limiting factor, these are very significant advantages. Fortunately, the presence of oxygen results in a strong absorption feature (due to ozone) just below 10 µm, near the peak of the thermal spectrum. Figure 1 shows the main O₂ and O₃ features in the Earth's spectrum. An unambiguous detection of ozone needs a spectrum with a resolution of 1 µm and a signal-to-noise ratio of ~20.

A telescope for optical or infrared imaging should form a diffraction pattern with very low side-lobes at the radius of the planet. The side-lobe intensities depend on the size and geometry of the telescope pupil, the wavelength λ , controlled variations in transmission or reflectivity (apodization) and phase errors across the pupil. In general, a mirror will have phase errors on different spatial scales l. At an angle θ from a star, the scattering will be determined predominantly by errors of wavelength $l \approx$ λ/θ . If the surface errors on this scale are random, with an r.m.s. amplitude equal to $\delta(l)$, then the maximum realizable gain G, the intensity at the diffraction pattern centre compared with that at θ , is given approximately by

$$G(\theta) \simeq \frac{D^2 \theta^2}{8\pi \delta(l)^2} \tag{1}$$

where D is the telescope diameter. The exact value of G depends on the statistical character of the surface irregularities^{7,8}. The form of the residual scattered light will be a speckle pattern. Note that $G(\theta)$ depends only on the radiation wavelength through $\delta(l)$.

Consider first the problem of visible light imaging. The planet's image will be separated from that of the star by at least several times the radius of the first Airy minimum, depending on telescope aperture, and apodizing solutions have been developed in this domain capable of realizing extremely lowside-lobes. However, the tolerance on phase errors is very severe. Simply to overcome the photon noise of scattered starlight requires a gain of $\ge 10^7$ (ref. 5). Probably the most perfect mirror made to date is that of the 2.4-m-diameter Space Telescope, for which δ on the scale of 40 cm appropriate for visible light is ~5 nm (ref. 9). Thus, $G(0.25 \text{ arc s}) \approx 1.5 \times 10^4$, nearly 1,000 times smaller than required.

The only way to increase G is to decrease δ and/or increase D. For example, the goal of $G = 10^7$ could be achieved in an 8-m mirror if δ were 0.6 nm on a scale of 40 cm. The trouble is

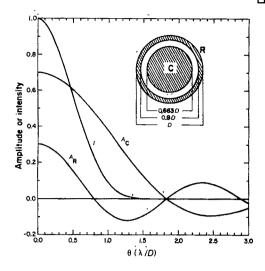

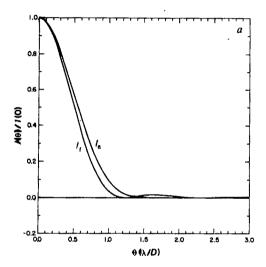

Fig. 2 Radial profiles of diffraction by a circular aperture apodized as shown, with a clear centre aperture C and outer annulus R. Curves $A_{\rm C}$ and $A_{\rm R}$ are the amplitudes from C and R, and I is the resulting intensity.

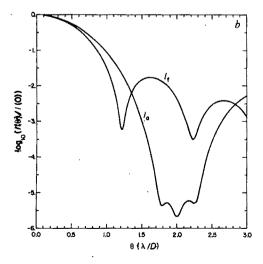

Fig. 3 Intensity of the diffraction patterns of the apodized aperture in Fig. 2 (I_a) and of a filled circular aperture (I_f) with the same outer diameter, plotted on different scales: a, linear; b, logarithmic. The intensities include broadening by bandwidth $\Delta \lambda / \lambda = 0.1$.

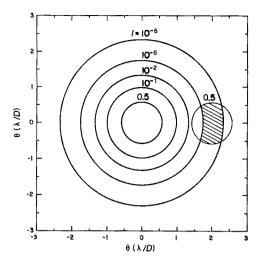

Fig. 4 Contour map of the intensity of the star's diffraction pattern, again with broadening by $\Delta\lambda/\lambda = 0.1$. The I = 0.5 contour of a planet's image is shown centred on the dark band, with the hatched area showing where the planet would be detected.

that even if the surface were finished to this accuracy, the remaining starlight is not a uniform background, but forms a speckle pattern. The speckles will look like a cluster of barely resolved stars of 21st magnitude, in which is hidden a 28th magnitude planet. Calibration of the 'star' field is almost impossible, as it is sensitive to path-length changes of only a few angstroms. These will probably arise as the telescope is rotated to move the planet's relative position or repointed to calibrate on another star. Burke⁵ argues that optical interferometry can control phase errors, but this will be a very difficult problem.

For these reasons we turn to the possibility of imaging the thermal emission, with greatly reduced requirements for gain and hence surface accuracy. The technical problems are still formidable, but if overcome will lead to a more secure observation. The telescope mirror must be large, at least 10 m in one dimension, to overcome the fundamental limits of diffraction at 10 µm wavlength. The mirror must be cooled to ≤80 K, to reduce the telescope thermal background to a level below that of the zodiacal background and scattered stellar radiation. Such cooling may well be possible by largely passive thermal control in an appropriate orbit. For example, since the cryogen was exhausted, the IRAS (Infrared Astronomy Satellite) mirror has settled to a passive equilibrium temperature near 100 K (ref. 10).

The Airy diffraction pattern of the star formed by a simple round aperture of 10 m has a first minimum at 0.25 arc s radius, at 10 µm wavelength. However, the dark ring is not a deep or broad enough null to allow an effective search for a planet. After consideration of various single-mirror and array configurations, we find the best search beam can be made by a circular aperture apodized in a new way. A very dark and broad first minimum would be produced if the wave amplitude at the first dark ring were made to have an inflection with zero gradient. This can be approximated accurately by masking a circular pupil with an obscuring annulus, as shown in Fig. 2. The second dark ring of the outer transmitting annulus is arranged to coincide with the first dark ring of the inner disk. By correct choice of the mask radii (0.663 and 0.9 of the full radius), the amplitude slopes can be made nearly equal and opposite, yielding a very dark ring at radius $\theta = 1.83 \lambda/D$. For the planet at 0.25 arc s to appear centred in this ring at 10 µm wavelength, the full mirror diameter must be 16 m.

Fine-tuning of the relative areas of the disk and ring components can yield a moderately high gain over a wide band, or very high gain over a narrower band. To determine which is better, consider the background of zodiacal emission. It would clearly be optimum to have the residual stellar flux weaker than

this background. The most recent estimate from IRAS of the zodiacal flux at the ecliptic pole is a grey body at 275 K with optical depth $\tau = 7.1 \times 10^{-8}$ (G. Rieke, personal communication). If the planetary system under observation is similar to the Solar System, and is viewed perpendicular to its orbital plane, its own zodiacal emission will be twice as bright, vielding a total background τ of 2.13×10^{-7} . The spatial resolution element d Ω of the apodized telescope is $(\lambda/D)^2$, and in this element, for $\lambda = 10 \,\mu\text{m}$ and $D = 16 \,\text{m}$, we obtain a photon flux λN_{λ} of 850 photons m⁻² s⁻¹. This is 5×10^{-6} of the 10- μ m stellar flux of Fig. 1. Thus the gain should be significantly better than 10⁵, to avoid stellar emission contributing to the background shot noise.

Figure 3 shows a version of the apodization which gives a gain of 3×10^5 , averaged over a dark annular ring in the image plane 1.73 $\lambda/D < \theta < 2.32 \lambda/D$. The amplitude passes through zero at three closely spaced radii. The profiles have been broadened by a bandwidth $\Delta \lambda / \lambda = 0.1$. The central maximum is only a little broader than for the unapodized case, while high throughput is maintained 63% that of the unapodized full aperture.

The signal-to-noise ratio of such a telescope can be computed with reference to Fig. 4, which shows the 50% contour of a planet's image seen against the star's diffraction pattern. Radiation from the planet would be measured with the shaded region of solid angle $d\Omega = 2.2 \times 10^{-13}$ sr, which contains 25% of its total flux. Assuming a combined telescope and detector efficiency of 50%, the signal from the Earth at 4 pc would be 30 electrons s⁻¹. Zodiacal emission would give a signal of 3,000 electrons s⁻¹, while the scattered light from the star in the same region would give a signal of 900 electrons s⁻¹. The shot noise fluctuations of the combined background would thus be ± 62 electrons s⁻¹, and the signal-to-noise ratio about unity in 4 s of integration. An integration of 30 min would be needed to achieve the desired signal-to-noise ratio of 20. We would use two-dimensional imaging detector with a tunable filter. The initial search would be made at one or a few wavelengths at the 0.25 arcs radius, and at larger radii with smaller or more conventional apodizing masks. Once a planet is located and an ephemeris calculated, its spectrum would be accumulated over a few hours by repeated scanning through the full wavelength interval.

Given an apodization solution that can, in theory, give very acceptable performance, we return to a discussion of mirror surface accuracy. For the 16-m mirror, phase errors on a scale of l=8 m will be the most important, and from equation (1) for $G = 10^6$ these should be <4 nm for the theoretical apodization gain of 3×10^5 not to be compromized. The mirror needs comparable accuracy to that of the Space Telescope on large scales, but could be less perfect on smaller scales. A 16-m mirror to these specifications could be assembled in space from lightweight rigid segments prefabricated on the ground. These should be made from glass that has zero expansion coefficient at the ~80 K operating temperature, such as high silica borosilicate with a conveniently low fusion temperature of ~1,200 °C (ref. 11). The placement of the segments to form the large surface would have to be accurate to 4 nm. Such accuracy could be achieved by a servo loop to adjust the segment heights to correct errors in the star's diffraction pattern measured in ultraviolet light. This pattern is the same at different wavelengths, except that the effect of phase errors is magnified as the square of the wavelength ratio. Small phase errors in the 10-µm pattern will give error signals magnified by 1,000 at 3,000 Å and 10,000 at 1,000 Å, provided that spatial variation in ultraviolet and infrared reflectivity are controlled to the 0.1% level. The effect of 4 nm surface errors will be to introduce speckle structure in the dark ring at ~10 times the planet brightness. In the initial search this structure must be calibrated out by rotation of the telescope.

The search for earthlike planets and oxygen could conceivably be carried out with a less expensive, one-dimensional telescope configuration, but with inferior results. Consider, for example, a 4 m by 12 m rectangular mirror launched in the space shuttle

and apodized in a manner similar to that described, to give a response with two very dark fringes 0.25 arc s on either side of the central bright fringe. The planet could, in principle, be detected by rotation to compare the brightness of the two fringes, in the manner proposed by Bracewell and MacPhie⁴. However, it appears that the full dark ring formed by a round telescope will give a much better chance to reject spurious signals from phase errors, as well as more pixels. Furthermore, the inferior resolution solid angle of the smaller collecting area would result in a signal-to-noise ratio limited by zodical background which is four times worse. Each spectral point would thus take 16 times longer (8 h) and be less secure.

It is interesting that consideration of a single observational goal has led to a very specific solution: a round 16-m-diameter telescope, cooled to <80 K and with a figure essentially diffraction-limited in visible light. Its size is similar to that proposed for the large deployable reflector (LDR) project, but it is cooled and of higher surface quality. It would bring great power to many of the most fundamental problems of astrophysics, in addition to the search for life. We believe it merits further study as part of NASA's long-range plans.

A corollary of this work is that life on Earth could have been detected during the past 10° years from thousands of planets beyond the wave of man-made radio emission, by an infrared telescope of 100-200 m diameter.

We acknowledge valuable discussions of this work with Bob Brown, Bernie Burke and Frank Low. Research in Innovative Optics for Space has been supported at Steward Observatory by NASA grant NAGW-121.

An explanation of the east-west asymmetry of Io's sodium cloud

Nicolas Thomas

Rock Cottage, Kinnerley, Oswestry SY10 8DF, UK

Since the discovery of a cloud of neutral sodium atoms accompanying the jovian satellite, Io, in its orbit1, asymmetries of part of the cloud (region B)2 have often been noted3-6. Brightness variations with orbital longitude^{3,4} and asymmetries found by comparing images taken at orbital longitudes differing by 180° (ref. 5) have been explained as effects of solar radiation pressure7. Given that the vast majority of neutrals precede Io in its orbit, and that sputtering of Io is the principal source mechanism, Matson et al.8 postulated a hemispherical source centred 60° towards the sub-Jupiter point from the centre of the leading hemisphere to explain the general cloud shape. However, soft collisions with plasma ions may be important and call for a reassessment⁹. I show here that, given reasonable assumptions, the east-west brightness asymmetry can be explained by temporal changes in the number of emitting atoms in the cloud caused by atmospheric shielding of the surface. Three types of SO₂ atmosphere have been proposed for Io. Matson and Nash¹⁰ used the phenomenon of sub-surface cold-trapping to produce a model in which sputtering of the entire surface is possible. Following measurements of sputtering yields¹¹, it has been shown^{12,13} that surface sputtering alone cannot balance observed loss rates from the plasma torus and hence cannot maintain the observed stability.

The second type of model¹²⁻¹⁴ is an atmosphere in which the sputtering ions cannot strike the surface but do sputter material from the atmosphere. In atmospheric sputtering, the bound gas serves as a target, and recoil collisions occur, leading to escape. Kumar himself¹⁴ recognizes the problems with this type of model. First, neutral sodium has to be present in large quantities in the atmosphere, where it is liable to rapid charge exchange. To reproduce the size of the cloud, a surface electron concentration 5 times higher than observed 15,16 was found to be necessary in this model. Second, sputtering of the polar caps would not be possible, and rapid atmospheric mixing 13 due to pressure gradients would lead to bright cap formation, contrary to observation 17.

The third type of model^{18,19} is based on the equilibrium vapour pressure (EVP) of SO₂ controlling the atmospheric pressure. As Io's surface temperature varies from <87 K on the night side to > 130 K at the sub-solar point, and the EVP of SO₂ increases by seven orders of magnitude over this range 10,20 , the atmosphere is characterized by high pressures and atmospheric sputtering on the day side and low pressures and surface sputtering on the night side and at the poles. Thus at eastern elongation, 90° beyond superior conjunction, the co-rotating plasma strikes the night side and removes sodium and SO₂ from the surface, whereas at western elongation the plasma cannot strike the surface (except at the poles), and hence SO₂ in larger quantities is removed from the atmosphere. This idea implies an asymmetrical sodium source which should be reflected in changing numbers of atoms in the cloud and consequent brightness variations. Some authors, citing ref. 6, have suggested that the cloud is strikingly symmetrical between eastern and western elongations^{9,21}, and that therefore an anisotropic source is not appropriate. However, the work of Murcray and Goody⁶ is not conclusive. They state that "there may be a slight trend toward lower intensities in the exposures on the western side of Jupiter" (see also refs 3 and 4) and that they "are unable to judge from the data themselves whether or not we are seeing a real temporal change in the cloud". Thus an asymmetrical sodium source is not ruled out.

A simple model may be used to determine whether the idea is consistent with observations. The total ejection rate is taken as

$$\Gamma = kA \tag{1}$$

where k is the ejection rate per unit area. A is the cross-sectional area of Io exposed to the sputtering, as defined by

$$A = \frac{\pi r^2 - E}{2} (1 + \cos(\phi + \Phi)) + E \tag{2}$$

where

$$E = 4 \int_{-\infty}^{r \sin(\pi/2 - \theta)} (r^2 - y^2)^{1/2} dy$$
 (3)

in which θ is the latitude above which no protection is afforded to the surface at any time, ϕ is the angular departure of Io from eastern elongation (Sun-centred coordinates) and r is the radius of Io. Φ (see Fig. 1) is an angle accounting for the process described by Cummings et al.²² which invokes neutral mized near Io's surface as a source of sputtering ions. Interaction with the co-rotating electrical field would concentrate sputtering towards Io's inner face, thus explaining the relatively large number of sodium atoms inside Io's orbit. Inclusion of this term may be consistent with Io's longitudinal albedo asymmetry²³, showing the darkest hemisphere to be centred \sim 45° nearer the

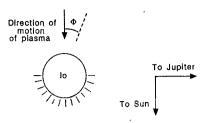

Fig. 1 At eastern elongation ($\phi = 0^{\circ}$), the higher-density day-side atmosphere (shaded) is sheltered from the incident plasma and affords no protection to the surface. The Φ term in the calculation accounts for the process described by Cummings et al.²².

sub-Jupiter point than the trailing hemisphere. Darker colour both on this hemisphere and at the poles is associated with radiation damage²⁴⁻²⁶ and lack of surface SO_2 due to surface sputtering²⁷⁻²⁹. In general accordance with these observations, Φ is taken to be $\pi/6$.

The equation for the total loss rate is taken as

$$\Xi = \frac{n(1 - e^{(-t/L)})}{t} \tag{4}$$

where L is the mean lifetime of sodium atoms in the cloud before ionization, n is the total number of atoms in the cloud and t is the time step. Thus the change in the total number of sodium atoms is

$$\frac{\mathrm{d}n}{\mathrm{d}t} = \Gamma - \Xi \tag{5}$$

Shemansky³⁰ calculated a value for L of 1 h; however, it has been suggested that this is only approached in the immediate vicinity of Io⁹. Arguments in favour of longer neutral sodium lifetimes are supported by high-resolution profiles of the sodium D_2 -line showing high-velocity wings dependent on Io's orbital phase. Implied velocities are as high as 18 km s^{-1} with respect to Io, blueshifted at eastern elongation and redshifted at western elongation³¹. A sputtered sodium atom would take just over 6 h to reach the leading edge of the cloud at this speed. Brown et al.⁹ consider that the average sodium lifetime in region B is between 5 and 10 h. They also point out that the velocity distribution and cloud structure can be explained by elastic collisions. The wings on the D_2 -line profiles are strongest when Io is on Jupiter's magnetic equator³¹. As the peak ion density in the torus is on or near the magnetic equator³², the higher density should lead to more collisions and hence more sodium atoms at high velocity.

Figure 2, calculated by step-by-step integration of equation (5) (for $t \ll L$) with a shooting method, shows a brightness reduction consistent with 20-25% brightness asymmetries^{3,4}. Furthermore, the latitude above which surface sputtering can occur on the day side is consistent with that predicted by Pearl et al.'s¹⁸ EVP atmospheric model.

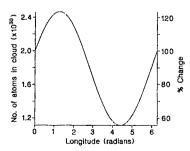

Fig. 2 Brightness variation as a function of orbital phase for Io's sodium cloud, assuming an anisotropic source caused by atmospheric shielding of the surface. Longitude is measured from eastern elongation. Day-side surface exposed to co-rotating plasma at latitudes greater than 75°; average sodium atom lifetime, 6.0 h.

Figure 3a shows the brightness reduction as a function of lifetime, maintaining the exposure latitude at 75°, and Fig. 3b shows the result of keeping the lifetime constant while varying the exposure latitude. Increasing the lifetime requires an increase in the exposure latitude to achieve the same brightness change. Thus sodium lifetimes and exposure latitudes are tightly constrained but are consistent with the EVP atmospheric models, surface brightness and SO₂ distributions and sodium velocity distributions. For example, Φ values $> \pi/4$ are inconsistent with observation. For $\Phi = \pi/6$, the lifetime is constrained to lie between 3 h ($\theta = 60^{\circ}$) and 8 h ($\theta = 90^{\circ}$). The lower limit is inconsistent with the velocity distribution. Near-direct sputtering of

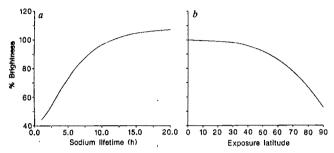

Fig. 3 Brightness changes at western elongation as a function of a, sodium atom lifetime (exposure latitude = 75°) and b, exposure latitude (mean sodium lifetime = 5 h). Brightness at eastern elongation = 100%.

the trailing hemisphere ($\Phi = 10^{\circ}$) gives a looser bracket for the lifetime of $10 \pm 4 \text{ h}$.

Further temporal variations may result from volcanic activity, in which the driving volatile may protect the surface near the vent, leading to a short-timescale reduction in brightness of the cloud.

To estimate whether surface sputtering can produce sufficient quantities of sodium atoms to populate the cloud and, ultimately, the torus, knowledge of the sputtering yields is required; however, a rough value can be obtained by using the yields estimated for SO₂ (ref. 11). Taking the O⁺ ion impact yield of 50 as a lower limit for the lower-mass Na atom and estimating that ~3% of the sputtered material would escape from Io, then 1.5 Na atoms per impact would escape from a pure sodium surface. Using 2×10^{9} m⁻³ for the ion concentration in the , the number of sodium atoms produced would be 1.7×10^{14} m⁻² s⁻¹. Multiplying by the cross-sectional area of Io gives a total of $\sim 1.8 \times 10^{27}$ Na atoms s⁻¹ produced from one hemisphere if the surface were 100% sodium. Kumar¹⁴ states that the required rate to populate the cloud is 8.3×10^{25} atoms s^{-1} . This allows us to put a limit of $\sim 4.7\%$ on the percentage surface coverage of sodium. However, Kumar's required population rate is relatively low, a value of $\sim 10^{27}$ Na atoms s⁻¹ having been quoted elsewhere⁹. Unless the sputter yield is substantially higher (by more than a factor of 4), surface sputtering would be capable of supplying this quantity only if a high proportion of the surface were composed of sodium and its compounds, although the higher value makes the alternative case for atmospheric sputtering of sodium even more difficult.

I thank Michael Woolfson and Beryl Leatham-Thomas for their assistance with this work.

A class of narrow-band-gap semiconducting polymers

Samson A. Jenekhe

Honeywell Inc., Physical Sciences Center, Bloomington, Minnesota 55420, USA

Scientific interest in electrically conducting polymers and conjugated polymers in general has been widespread among workers in polymer science, chemistry, condensed matter physics, materials science and related fields since the discovery of doped conductive polyacetylene^{1,2}. Many doped conducting organic polymers with conductivity spanning the range from insulator to near-metallic (~10⁻¹⁵-10³ ohm⁻¹ cm⁻¹) are now known¹⁻¹³. Of prime importance and fundamental interest in the continuing experimental and theoretical search for new conducting, and perhaps superconducting, polymers is the achievement of small or vanishing values for the semiconductor band gap (E_g) , which governs the intrinsic electronic, optical and magnetic properties of materials. Existence of a finite $E_{\rm g}$ in conjugated polymers is thought to originate principally from bond-length alternation, which is related to the Peierls instability theorem for one-dimensional metals 14-17. Here I describe a novel class of conjugated polymers, containing alternating aromatic and quinonoid segments, whose members exhibit intrinsic band gaps as low as 0.75 eV, the smallest known value of $E_{\rm p}$ for an organic polymer.

Among conjugated polyenes, polyenynes, and related polymers, polyacetylene (PA), (-CH=CH-)_m, has the smallest band gap, with a value of 1.5 eV (ref. 3). Among the aromatic and hetero-aromatic conjugated polymers, polythiophene (PT) (Fig. 1a with X = S) has the smallest band gap, with a value of -2.1-2.2 eV (refs 8, 13). In the search for narrower-band-gap polymers, the strategy of substitution on existing main-chain polymers or formation of co-polymers has not generally been successful. An important exception is the annelated 3,4-benzo derivative of polythiophene, polyisothianaphthene (PITN), which has an E_g value of only 1.13 eV. Wudl et al. have attributed the difference in E_g values between PT and PITN to contribution of quinonoid resonance structure (Fig. 1b) in the case of PITN and a lack of such contribution in PT13. I have argued elsewhere that a large part of the ~ 1 eV difference in $E_{\rm e}$ values of PT and PITN is attributable to co-planarity of polymer repeating units in PITN and its lack in PT¹⁸. However, introduction of quinonoid character into the main chain of an aromatic conjugated polymer can be expected to reduce the band gap.

Fig. 1 a, Aromatic ground-state structure of hetero-aromatic polymers (for example, X = S, polythiophene; X = N - H, polypyrrole). b, Quinonoid ground-state structure of hetero-aromatic polymers of a. c, Ground-state structure of novel tunable, narrow-band-gap, conjugated polymers containing alternating aromatic and quinonoid segments, some of which exhibit the smallest E_g values known for organic polymers.

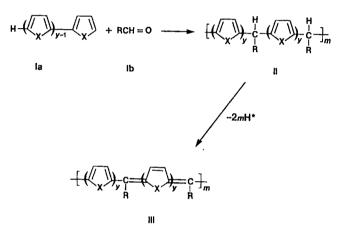

Fig. 2 Two-step synthesis of polymers with alternating aromatic and quinonoid segments, with quinonoid character Q = 1/2 (x = y in Fig. 1c).

In fact, we have already observed a similar effect in polycarbazoles 10 . Also, Bredas 19 has recently shown theoretically, using valence effective hamiltonian (VEH) calculations, that as quinonoid structure is introduced into polythiophene geometry (Fig. 1a, b) $E_{\rm g}$ decreases linearly with increasing quinonoid character 19 .

Figure 1c shows a class of hetero-aromatic conjugated polymers designed to incorporate aromatic and quinonoid segments in the main chain, which we hoped would exhibit small $E_{\rm g}$ values. This class of polymers displays several interesting general features:

(1) The quinonoid character is given in terms of integer molecular parameters (x, y) which could be subject to synthetic manipulation. Neglecting possible end-group effects, the fraction of the chain with quinonoid character is Q = y/(x+y). Thus, Q = 0, 1/2, 2/3, 3/4, 4/5, ... when y/x = 0, 1, 2, 3, 4, ... and Q = 1/3, 1/4, 1/5, 1/6, ... when y/x = 1/2, 1/3, 1/4, 1/5, The limiting cases of Q = 0 (y = 0 or $x \to \infty$) and Q = 1 (x = 0 or $y \to \infty$) correspond respectively to polymers with chain structures a and b (Fig. 1). The hypothetical polymer b, relative to a and polymers of intermediate compositions, has a lower but nonetheless finite E_g^{19} . The parameter Q could in principle be related to bond-length alternation Δr ($= d_1 - d_2$) by some function $f(\Delta r)$, where d_1 and d_2 are the C—C and C=C bond lengths respectively. The value of Q when $\Delta r = 0$ and of Δr when E_g is minimum would be of interest in understanding the origin of E_g in conjugated polymers.

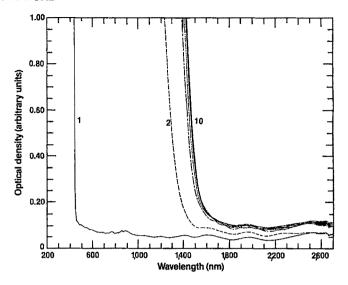

Fig. 3 Optical absorption spectra of thin films of polymer precursor PTTB (1), and conjugated derivatives (2-10), which are the polymers in Fig. 1c.

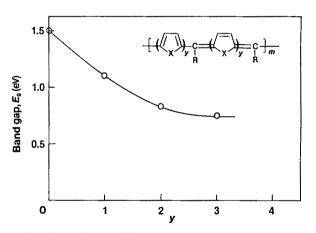

Fig. 4 The band gap $E_g(y)$ of the polymers in Fig. 1c with X = S, R = Ph and x = y. The E_g value at y = 0 is that of trans-PA.

- (2) The ground-state structure of this class of polymers is two-fold degenerate in the sense of *trans*-PA, when Q=1/2 or $x=y=1,2,3,4,\ldots$ In fact, when x=y=0 (Q=0) and R=H we obtain polyacetylene; however, the uniqueness of polyacetylene is preserved by its Q=0 value. Soliton excitations have been postulated for *trans*-PA on the basis of its degenerate ground-state structure²⁰. Thus, soliton excitations may be anticipated in the degenerate or symmetric (Q=1/2) polymers of Fig. 1c. However, it is unclear to what extent a finite Q will influence such excitations relative to *trans*-PA.
- (3) If the hetero-atom (X) is neglected, the polymer backbone is essentially an alternating co-polymer of *trans-cisoid* and *cistransoid* forms of polyacetylene.
- (4) Doping in aromatic (for example, poly-p-phenylene) and hetero-aromatic (Fig. 1a) polymers leads to polarons and bipolarons as the charged species, presumably by increasing the quinonoid character (Q) of the chain^{21,22}. As the present class of polymers already has Q > 0, it is uncertain how much more, if any, quinonoid character can result from doping.
- (5) As macromolecules, these polymers have an unusual 'expandable' constitutional repeating unit (CRU), consisting of alternating aromatic and quinonoid segments. Conceivably, a material with a very high molecular weight (say 10^7) could result from a small chain length (say m=1), simply by increasing x and y. If such materials could be synthesized this suggests that the electronic and optical properties would be more sensitive to x and y than to the polymer chain length m. These

features and questions warrant a detailed theoretical investigation.

Polymers of the type shown in Fig. 1c, with x = y = 1, 2 or 3 (Q=1/2) have been experimentally realized for various X and R by a two-step synthetic technique, shown in Fig. 2. First, non-conjugated precursor polymers containing alternating sp³ carbon atom (-CRH-) and hetero-aromatic conjugated units D were synthesized by condensation polymerization of the appropriate monomer, dimer or trimer (Ia) with aldehydes (Ib), where D is 2,5-thiophenediyl, $5,5'-\alpha$ -bithiophenediyl or $5,5'',\alpha$ terthiophenediyl. Second, the precursors (II) were converted to the conjugated polymers with alternating aromatic and quinonoid segments (III) by oxidative elimination of the bridge hydrogens. This two-step synthesis could also be used to achieve the asymmetric polymers of Fig. 1c; that is, those with $Q \neq 1/2$. Note that the basic linear structure of the conjugated polymers (III) is the same as that of the precursors (II); the structure of the precursors (II) was readily established by infrared spectra. The precursor polymers have been characterized by infrared and electronic spectra, elemental analysis, studies of molecular weight, and thermal analysis. Evidence of the elimination of the bridge hydrogens is provided principally by infrared and electronic spectra; insolubility of polymers III compared to polymers II provides additional proof of elimination. Details of the syntheses of the conjugated polymers and their precursors are described elsewhere (refs 18, 23 and S.A.J. in preparation). The smallest band gaps were obtained with X = S. Also, E_{α} values were less sensitive to the side-group R.

Figure 3 shows the optical absorption spectra for thin films (\sim 0.1-0.2 µm) of a polymer with R = phenyl, X = S and x = y = 3. Curve 1 is the optical absorption spectrum of the polymer precursor, poly- $(5,5',\alpha$ -terthiophenediyl benzylidene) (PTTB). Curve 2 is that of a conjugated derivative (Fig. 1c) which has an $E_{\rm g}$ of 0.83 eV (1,500 nm) and corresponds to the product of elimination after 7.1 min of reaction. On exhaustive elimination (curves 2-10) the band gap narrows to a constant value of 0.75 eV (1,650 nm). Similar results of band-gap narrowing to a constant value during elimination have been obtained for x =y = 1 and 2: y = 1, $E_g = 1.1$ eV; y = 2, $E_g = 0.83$ eV.

Figure 4 shows the band gap as a function of y for X = S and x = y. The point shown at y = 0 is that for trans-PA; this is because the general polymer repeating unit shown in Fig. 3 contains 8y + 2 carbon atoms in the main chain, which naturally reduces to polyacetylene in the limit y = 0. The asymptotic value of $E_g(y)$ is ~ 0.7 eV, which is already closely approached at y=3.

As expected, the proposed polymers do exhibit narrow band gaps. Although the quinonoid character Q qualitatively explains why $E_{\rm g}$ is smaller in this class of polymers, relative to PT, it does not explain why the band gap decreases with y at a constant Q, as observed. If there is a linear relationship between $E_{\rm g}$ and Q, it will be approximately $E_g = 2.2 - 2.05Q$, using the band gap of PT (2.2 eV, Q = 0) and the $E_{\rm e}$ value of 0.15 eV calculated for Q = 1 by Bredas¹⁹. The expected E_g value of 1.18 eV at Q = 1/2is close to the 1.1 eV found for y = 1, but the other values of the band gap at Q=1/2 cannot be explained by this linear equation at all. This is due to the degeneracy of the case Q = 1/2. Both the generally small band gaps in this class of polymers and the decrease of E_g with y can be explained in terms of the more primitive concept, the bond-length alternation Δr . The decrease of E_{α} with y is consistent with the decrease in Δr with expansion of the polymer repeating unit. From the theoretical calculations of Grant and Batra¹⁶ for trans-PA and those of Bredas¹⁹ for PT, a linear relationship of the form $E_g = E_g^0 + b\Delta r$ appears to hold. We have obtained the same value of b = 11.50 eV/Å from the two different calculations 16,19 ; however, $E_g^0 = 0$ for trans-PA¹⁶ and $E_g^0 = 0.705 \text{ eV}$ for PT¹⁹. This linear equation and the observed band gaps give estimated bond alternations of 0.034, 0.011 and 0.004 Å for y = 1, 2 and 3, respectively, compared to 0.13 Å for PT. It will be interesting to compare these estimated bond alternation values with those

computed or measured directly. Even from these estimates it is clear that nearly uniform bond lengths are attained at y = 3 and yet the band gap is as high as 0.75 eV due primarily to E_a^0 Existence of a finite E_g^0 further distinguishes aromatic and hetero-aromatic conjugated polymers from polyenes¹⁹, and raises the question of its origin, as only the amount above E_{\bullet}^{0} can be attributed to bond alternation. Narrower band gaps would imply negative bond alternation ($\Delta r < 0$), in which carbon-carbon double bonds are longer than single bonds. In principle, as the calculations of Bredas suggest¹⁹, the proposed hetero-aromatic polymers (Fig. 1c) with $Q \to 1$ could exhibit band gaps smaller than E_g^0 , but such members of this class of polymers have yet to be synthesized.

Obviously, other hetero-aromatic or aromatic polymers with structures similar to Fig. 1c, and hence similar properties, can be expected when the hetero-aromatic units, $(C_4H_2X)_{y,x}$, are replaced by phenyl (Ph), p-phenylene oligomers, or other groups capable of both aromatic and quinonoid bonding structures. After we had already synthesized the polymers described here we became aware of the theoretical work of others, predicting a narrow band gap for a structurally related hypothetical (not yet synthesized) polymer. Boudreaux et al.²⁴ have calculated a band gap of 1.17 eV and predicted the existence soliton excitations in poly-p-phenylenemethine, $(-Ph-CH=Ph=CH-)_m$

Extraordinary effects of mortar-andpestle grinding on microstructure of sintered alumina gel

W. A. Yarbrough & Rustum Roy

Materials Research Laboratory, The Pennsylvania State University. University Park, Pennsylvania, USA

The use of the mortar and pestle in the laboratory dates back to the earliest attempts to understand and use the materials around us. Even now, it is difficult to imagine an alternative to crushing and grinding for the preparation of many samples. Traditionally, mortar-and-pestle mixing or grinding has been held to be a relatively mild and controlled process, although it was recognized that the grinding of materials harder than the material of the mortar and pestle would result in some contamination. Thus, good practice forbade grinding of, for example, mullite and alumina in agate mortars. That this technique is not so innocuous was demonstrated by Dachille and Roy1 with respect to the stresses generated. They showed that phases usually obtained only at 10-20 kbar can be obtained metastably by simple grinding in a laboratory mortar. There are numerous examples of solid-state phase transformations being produced by prolonged or intense comminution², two of the best-documented cases of stress/shear-induced transformation being the conversion of calcite to aragonite¹, and of quartz to amorphous silica^{3,4}, both by prolonged grinding in a laboratory mortar and pestle. Here we show that the very small amounts of material generated by the wear of mortar and pestle surfaces by even mild grinding can also have substantial effects on the microstructure and transformation kinetics of certain ceramic systems so treated.

Materials prepared by the sol-gel method are typically obtained as non-crystalline or poorly crystallized metastable solids which may then be calcined for densification and/or transformation to a more stable crystalline phase. In the preparation of dense non-crystalline solids (glasses), uncontrolled crystallization or devitrification is undesirable, as this usually leads to a loss of mechanical integrity and other desired properties, such as transparency. In other materials, where a given stable crystalline phase may be the desired product, the kinetics of transformation and the microstructure of the material obtained can be controlled by 'seeding' with the desired phase or with chemically dissimilar materials having, or readily transforming to, the desired structure.

Seeding with crystals of the expected or desired phase has long been used as an aid in the study of phase equilibria, and the importance of even minor amounts of a second phase, isostructural with a stable phase of the composition under study, has already been noted^{5,6}. In particular, we have reported the remarkably enhanced transformation kinetics obtained by seeding sol-gel-derived materials⁷⁻¹⁰. This may well turn out to be a route to a new class of crystalline solids: nanocomposites (dior multiphasic solid aggregates), where the size range of the monophasic regions is ~1-100 nm. One of the striking properties of a structurally diphasic xerogel (for example, boehmite sol mixed with an α -alumina sol) is the solid-state epitaxy which occurs on heating, with considerably accelerated kinetics. Thus, Fig. 1 (taken from ref. 9) compares the differential thermal analysis (DTA) of a monophasic boehmite sol with that of a diphasic sol of boehmite and various amounts of α -alumina. Seeding with amounts as small as 0.08 wt % results in a marked lowering of the transformation temperature. Moreover, there is a marked change in the microstructure of the alumina formed.

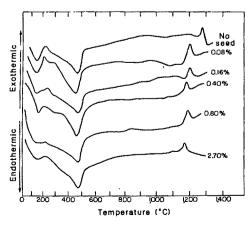

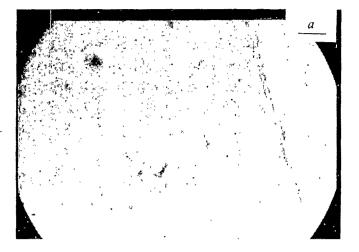

Fig. 1 DTA results showing the effect of seeding with various amounts of α -alumina on the transformation temperature of boehmite gel.

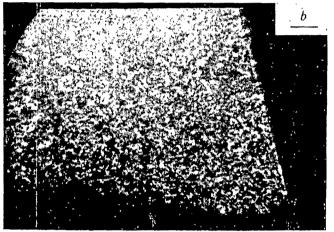

Fig. 2 Boehmite gel fragment prepared from water 'ground' in Diamonite mortar and pestle as seen after calcination at 1,200 °C for 2 h: a, Bright-field transmitted light; b, crossed polars. Scale bars, 10 µm.

In the unseeded material, monocrystalline cells $\sim 10~\mu m$ across are formed, whereas in the seeded material, the grain size is $<1~\mu m$ (ref. 10).

The mortar and pestle experiment was conducted using a Fisher Scientific Co. 'Diamonite' (corundum) mortar and pestle. After thoroughly cleaning the mortar and pestle, 200 ml of deionized water was added to the mortar. The water was slowly 'ground' in the mortar using only light to moderate pressure for 5 min. This water, slightly turbid with suspended detritus from the wear of the mortar and pestle surfaces, was then used to prepare a boehmite (aluminium oxide monohydrate) sol using 13.90 g of a commercially available microcrystalline boehmite. (Dispereal, Remet Chemical Co.) The boehmite was peptized using 15.0 ml of 1.00 M HNO₃; the sol was then dried at 90-95 °C to produce a boehmite xerogel. A second batch of xerogel was prepared in precisely the same manner using the same lots of material (water, acid and boehmite), the only modification being the use of a mortar and pestle of agate instead of Diamonite. Fragments of these xerogels were lightly crushed in an agate mortar and pestle. Calcination was performed in air using a Lindberg model 51524 furnace equipped with a model 59256-E1 controller (Lindberg Co.). This furnace uses exposed MoSi₂ elements and had been modified by installing a type S thermocouple positioned just above the sample for accurate temperature measurement. The maximum calcination temperature was 1,200 °C for a period of 2 h, which is sufficient to convert all of the material to α -alumina. The powders were dispersed in immersion oil and examined with a polarizing microscope.

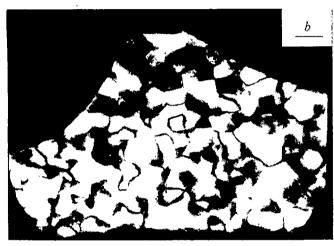

Fig. 3 Boehmite gel fragment prepared from water 'ground' in agate mortar and pestle as seen after calcination at 1,200 °C for 2 h: a, Bright-field transmitted light; b, crossed polars. Scale bars,

Alpha aluminium oxide (α -alumina) is anisotropic and uniaxial negative. Assuming that a sufficient crystallite size is attained on transformation, its birefringence makes observation in a polarizing microscope relatively easy. Figures 2 and 3 show transmitted-light photomicrographs (Figs 2a and 3a in brightfield transmitted light; Figs 2b and 3b using crossed polars) of the calcined powders. Transformation occurs by the nucleation and growth of the α phase in a matrix of very finely divided and poorly crystallized transitional aluminas (δ and θ). The microstructure exhibited in Fig. 2 is identical to that obtained in a xerogel seeded with α -alumina or with materials having the corundum crystal structure; that seen in Fig. 3 is identical to that seen with unseeded or non-isostructurally seeded gels.

Scientists almost universally use milling or grinding in a mortar and pestle as a means of preparing powdered materials, in industry as well as in the laboratory. It is so routine that in many cases no report is made of the materials and methods used¹¹. Enhanced transformation kinetics and nucleation frequency in milled materials have been variously attributed to particle size effects¹² and possibly lattice strain¹³. Dynys and Halloran¹³, in fact, considered and rejected the possibility that detritus from milling was responsible for these effects. In their experiment, α -alumina milling debris was collected, dried and dry-mixed (at 1 wt%) with powders obtained from the calcination of ammonium alum. Pressed pellets were prepared and fired in air. No effect could be seen either by transmission electron microscopy or by comparison of the transformation kinetics of doped and undoped material. Assuming that the nature of the interface between seed and bulk phase, and the uniformity of seed distribution, are of controlling importance, it is not surprising to find that the efficacy of seeding depends on how the seed phase is produced and introduced to the bulk material. Effects due to the method of seed introduction have been observed previously¹⁴. This demonstration of the power of trace contaminants introduced by grinding has led us to question our common laboratory and commercial practice

Crustal structure of the northern Alpha Ridge beneath the Arctic Ocean

D. A. Forsyth*, I. Asudeh*, A. G. Green* & H. R. Jackson†

* Lithosphere and Canadian Shield Division, Geological Survey of Canada, 1 Observatory Crescent, Ottawa, Ontario, Canada K1A 0V3 † Atlantic Geoscience Centre, Geological Survey of Canada, Bedford Institute of Oceanography, PO Box 1006, Dartmouth, Nova Scotta, Canada B2Y 4A2

Beneath the Arctic Ocean, the Alpha Ridge complex is the principal tectonic feature between the Canada Basin and the Lomonsov Ridge. Here we report on analysis of seismic refraction data along the Alpha Ridge and within the basin area 175 km to the north (Fig. 1), which, together with geological and aeromagnetic constraints, indicates that the Alpha Ridge is characterized by regions of continental-like thickness but has probably resulted from an oceanic mode of development. The ridge flank thins towards the North Pole but may extend as far north as 88° N, and is therefore >500 km wide in the region near 110° W. Consequently, south of the pole along 110° W, typical oceanic crust beneath the eastern Makarov Basin may be present only locally, if at all. Similarities between the velocity structures of the Alpha Ridge and the Iceland area suggest that the Icelandic structure may be a currently active analogue for the Alpha Ridge.

The 1983 CESAR (Canadian Expedition to Study the Alpha Ridge) crustal refraction survey consisted of a 200-l.m 'strike' line with 7-8-km station spacing along the CESAR South Ridge (C.S.R. in Fig. 1) of the Alpha complex, a parallel 120-km-long 'basin' line north of 87° N, in what we considered to be the Makarov Basin, and a 175-km 'dip' line connecting the other two lines. In addition, an 80-km 'camp' line with an effective spacing of 1-2 km was recorded along the CESAR North Ridge (C.N.R. in Fig. 1). All lines were effectively reversed, the strike line was also recorded to each end from a central shotpoint. The camp and basin lines were shot along the line and recorded at the ends. Multi-element arrays1 on the ice surface recorded

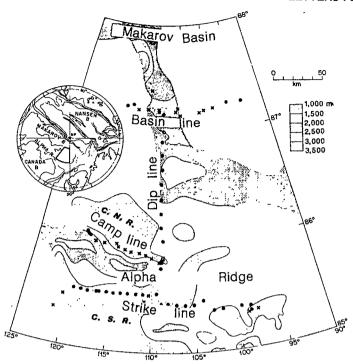

Fig. 1 Location of the CESAR refraction profiles. ●, Recorder location; ×, shot location.

A a a b a construction of the construction of

Fig. 2 CESAR strike line. A, comparison of section shot from west end (b) with first-arrival and PmP reflection synthetic section (a). The data (b) are shown with true amplitudes, after application of a bandpass filter (2.5-10.0 Hz). B, Velocity model derived from analysis of reversed strike line data. energy from 100-500-kg shots detonated at depths of 100 m (end shots) to 200 m (line shots). We report here the crustal models determined from the strike and basin line data sets. Interpretations of the dip and camp line data are consistent with these models (I.A., A.G.G. and D.A.F., in preparation).

As in most marine surveys, reverberations in the water and sediment layers are common in the CESAR data, and secondary energy arriving later but with apparent P-wave velocity similar to that of the first arrivals can be traced up to several seconds after the first arrivals (Fig. 2A). A thorough study of the nature of these multiples using synthetic seismogram modelling techniques produced water depth estimates in good agreement with known values, and determined that sediment cover was generally <1 km over the ridge area. Sediment thicknesses varying from zero to 1 km were observed independently from air-gun reflection data gathered at the main camp on the ice as it drifted from the central region of the strike line to C.N.R.² (Fig. 1).

The first-arrival waveform of the strike line data remains remarkably similar and continuous for distances up to ~ 100 km. Within this range, the first-arrival waveforms recorded from the central and eastern shotpoints are similar to the data section in Fig. 2A. There is little evidence of reflected arrivals from midor upper-crustal boundaries; the data suggest considerable lateral homogeneity in the upper crust. At distances > 100 km the first-arrival waveform uniformity is gradually lost to the effects of deeper lateral velocity variations and reflected arrivals from the crust-mantle boundary. The maximum reflected energy is concentrated in the distance range 150–180 km. The wideangle reflected energy and the cross-over to first-arrival velocities of ~ 8.1 km s⁻¹ in the distance range 180–200 km require a relatively thick crustal section.

In Fig. 2A, the synthetic section generated³ from the western shotpoint through our proposed crustal model is compared to the observed data. The strike line model results from synthetic seismogram modelling of the sections from each end of the line and the data recorded from the centre shotpoint. Overlapping and reversed ray paths demonstrate that the model is relatively

well constrained to a depth of \sim 24 km. The exact shape of the anomalous triangular zone of lower average velocity, the velocity structure of the lower crust and the depth of the crust-mantle transition are more weakly constrained. In Fig. 2B the dashed and dotted lines represent velocity or velocity gradient changes (heavy dashes indicate regions constrained by ray-trace modelling). The crust-mantle transition is shown as a solid line to represent the velocity step required to produce the wide-angle reflections in Fig. 2A.

Figure 2B includes the time delays required by variations in water depth and by our best estimates of sediment cover thickness. Beneath the sediments, the upper crust is characterized by a laterally uniform velocity of 5.1 km s⁻¹ and a gradient of $\sim 0.23 \text{ s}^{-1}$. At 9 km depth the velocity gradient diminishes to 0.05 s⁻¹ and 0.10 s⁻¹, in the eastern and western regions respectively, to satisfy times and amplitudes of first-arrival energy at distances <90 km. These gradients lead to mid-crustal velocities of 7.3 km s⁻¹ in the eastern part of the model, and upper-mantletype velocities of near 8.0 km s⁻¹ at similar depths in the west. The anomalous central region beneath the topographic high (Fig. 1), with a near-constant velocity of 6.8 km s⁻¹, is required to match times and amplitudes of first arrivals beyond 100 km. The depth of the crust-mantle transition cannot be determined confidently from first-arrival data because reversed upper mantle arrivals beyond a distance of 190 km were not well defined. However, given the control on mid- to upper-crustal velocity structure and the position and amplitude of first arrivals and wide-angle reflections (Fig. 2A), our modelling indicates a crustmantle transition at 38-40 km depth beneath the central and eastern regions and mantle-type velocities at 24 km depth beneath the western region. Tests using a range of plausible crustal and upper mantle velocities suggest a possible range of crustal thicknesses of 36-44 km for the eastern and central regions.

Reduced to a water depth of 2.5 km, reversed basin line sections to distances up to 60 km show a continuity of waveform remarkably similar to the strike line data (compare Figs 2A and

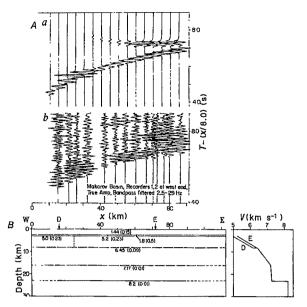

Fig. 3 CESAR basin line. A, comparison of section recorded at west end (b) with first-arrival and PmP reflection synthetic section (a). The data (b) are shown with true amplitudes, after application of a bandpass filter (2.5-29 Hz). B, Velocity model derived from analysis of reversed data obtained at each end of the line.

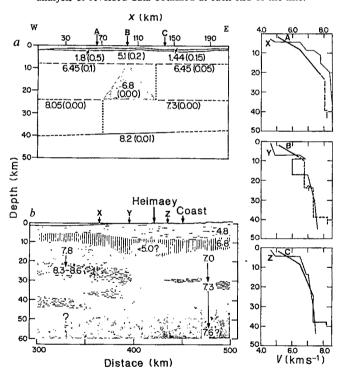

Fig. 4 Comparison of strike line velocity model (a) with model of Iceland-Reykjanes Ridge⁸ (b). Velocity-depth profiles A and X, B and Y and C and Z are compared at right.

3A). Beneath the sediments both data sets require a velocity of $5.1-5.2 \text{ km s}^{-1}$ and a gradient of $\sim 0.23 \text{ s}^{-1}$. Thus, the uppermost 15 km of the basin model (Fig. 3B) appear laterally homogeneous and closely resembles the western region of the strike line.

Features observed on the basin line but not observed on the strike line include indications of reflected energy closely following the first arrivals at ~ 30 km distance, and a large amplitude secondary event starting at ~ 60 km. The nearer source reflections result from the larger velocity difference in the western part of the basin (Fig. 3B). Note that the upper-crustal velocity gradient is uniform across the basin. We interpret the high-

amplitude secondary events starting at 60 km as reflections from the crust-mantle transition, similar to those observed on the strike line beyond 120 km. Again, the depth to the crust-mantle transition is poorly constrained, with our best estimate of 23 km being the mean of a range from 21 to 25 km.

Taylor et al⁴ point out that the short-wavelength magnetic anomalies in the area of Fig. 1 closely follow the bedrock topography of the Alpha Ridge, and they propose that ridge material extends farther south beneath the sediments of the Canada Basin than is indicated by the bathymetry. Similarly, the basin line, with a crustal thickness of ~23 km and a velocity structure similar to the Alpha Ridge, suggests that the ridge complex extends to ~200 km north of the strike line. These results support the suggestion⁵ that the Alpha Ridge complex extends almost to the edge of the Lomonosov Ridge, and is therefore >500 km wide in this region.

The upper-crustal velocity of 5.1 km s⁻¹ immediately underlying a thin sediment cover, the apparent lateral homogeneity along the strike of the ridge, the high-intensity magnetic anomalies⁴ and the vesicular, highly altered volcanic samples dredged from an Alpha Ridge scarp⁶ favour the identification of the upper crustal medium as oceanic layer 2. The greater lateral variation at mid- and lower-crustal depths seems to reflect a more complex tectonic evolution.

The continental-type thickness indicates that the Alpha Ridge, like the Ontong-Java and Manihiki plateaus of the Pacific plate⁷, is an oceanic plateau of problematic origin. Jackson² has outlined the similarity of the Alpha Ridge morphology and shallow structure to that seen on the Manihiki plateau. Certainly, the available geological and geophysical evidence suggests that both the Alpha and Manihiki features are characterized by an overthickened oceanic-type crust. A closer tectonic analogue to the Alpha structure may be Iceland today. Figure 4 shows a comparison of the velocity structure along the strike of the Alpha Ridge with the structure along the strike of the Mid-Atlantic system from the Reykjanes Ridge to Iceland. The lateral change from a structure characteristic of oceanic crust beneath the flank of the Reykjanes Ridge to a structure with 'anomalous mantle' beneath Iceland itself resembles the structure along the Alpha Ridge. Note that the crustal structures that have been derived from seismic refraction data may be compared only to depths of ~40 km; Icelandic structure below 40 km is not based on direct refraction data. Comparisons of velocity structures for particular sections of the respective models show:

(1) Thick oceanic sections beneath both the Alpha Ridge and Iceland, with typical layer 2 and layer 3 velocities and a similar velocity-depth profile for the thickened 'anomalous crust' beneath the active area of Iceland and the region beneath the eastern end of the Alpha Ridge profile (Z and C in Fig. 4). The greatest difference between the crustal responses is the interpreted wide-angle reflection coda that indicate significant energy return from a crust-mantle transition near 40 km depth beneath the Alpha Ridge. The absence of similar energy return from beneath Iceland is probably related to the present plume and spreading activity. Comparable activity would have ceased in the Alpha Ridge area during late Mesozoic times².

(2) A central zone (Y and B in Fig. 4), characterized in the Icelandic case by low-velocity regions representing possible magma chambers, and in the Alpha Ridge case by a region of lower velocity gradient. Neither Icelandic nor Alpha Ridge data sets can further resolve the zone of required time delay. In the Icelandic case the lower-velocity regions have been explained as zones of high melt concentration. In the older Alpha Ridge structure, the zone of lower velocity gradient may represent an ancient melt zone which has cooled to yield a higher velocity than in the much younger, still active zone beneath Iceland.

(3) A more normal oceanic velocity-depth profile for the flank of the Reykjanes Ridge and western part of the Alpha Ridge (X and A in Fig. 4), with upper-mantle velocities appearing in the 20-23 km depth range.

Note that, in general, comparable velocities are reached at ~3 km shallower depths on the Icelandic sections than on the Alpha Ridge sections. Although technique resolution may be debated, the results are consistent with the present elevation difference between Iceland (+1.5 km) and the Alpha Ridge (-1.5 km). It is suggested that most of the differences between the velocity-depth profiles may be accounted for by normal thermal decay and subsidence.

We greatly appreciate the valuable discussions and constructive critiques offered by Drs P. Morel-à-l'Huissier, I. Reid, J. R. Weber and M. J. Berry. This is Geological Survey of Canada contribution no. 11086, CESAR contribution no. 7.

Melting of a model chondritic mantle to 20 GPa

Eiji Ohtani*, Takumi Kato† & Hiroshi Sawamoto†

- * Department of Earth Sciences, Ehime University, Matsuyama 790,
- † Department of Earth Sciences, Nagoya University, Nagoya 464, Japan

Calculations of the thermal evolution of the Earth during accretion suggest that the outer layer may once have been molten, perhaps to a depth of 1,000 km or more^{1,2}. If such global melting did occur, fractionation processes could have produced a chemical stratification in the mantle. Recent technical developments in experimental petrology have made it possible to achieve temperatures in excess of 2,000 °C at a pressure of 20 GPa^{3,4}, thereby permitting studies of multi-component systems under conditions that prevail in the Earth's mantle. We have conducted melting experiments using a composition in the five-component system CaO-FeO-MgO-Al₂O₃-SiO₂ (CFMAS) corresponding to a model chondritic mantle, and find that the liquidus phase changes from olivine to majorite at a pressure between 12 and 15 GPa. The liquid coexisting with majorite at 20 GPa has a peridotitic composition. In addition, because the CaO/Al2O3 ratio of the liquidus majorite at 20 GPa is lower than that of the sub-solidus majorite, partial melting and majorite fractionation at the base of the upper mantle could produce a peridotitic liquid with a CaO/Al₂O₃ ratio greater than that of the chondritic starting material, consistent with current views on mantle geochemistry.

Cosmochemical studies (see, for example, refs 5, 6) suggest that the composition of the bulk Earth is close to chondritic in terms of the major lithophile and refractory elements, such as Mg, Si, Al and Ca. The bulk mantle may contain these elements in ratios close to chondritic. Assuming that the core is composed of iron with ~16 wt % light elements, a mass balance calculation⁷ gives a value of ~0.1 for the Fe/(Fe+Mg) (atomic) ratio of the mantle.

We therefore chose as our starting material a model chondritic mantle composition of 50.18 wt% SiO₂, 3.62% Al₂O₃, 7.16% FeO, 36.18% MgO and 2.86% CaO, in which the ratios of Mg, Si. Al and Ca are chondritic⁸, while the iron content is Fe/(Fe+ Mg) = 0.1. The samples were prepared by mixing the reagents and heating the mixture at 1,150 °C in an atmosphere with controlled oxygen partial pressure. The starting material after

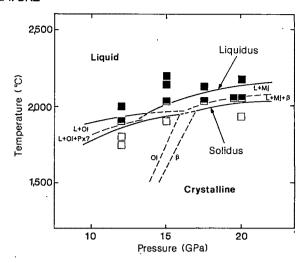

Fig. 1 Melting relations of a model chondritic mantle to 20 GPa. □, Sub-solidus; ≡, crystal+liquid; ≡, super-liquidus; L, liquid; Ol, olivine; Px, clinopyroxene; β , modified spinel; Mj, majorite.

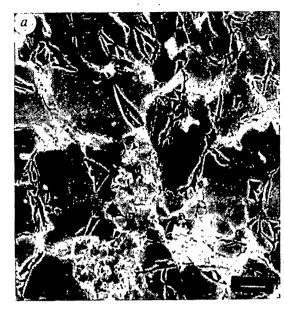

heating comprised olivine, pyroxenes and a small amount of anorthite.

The apparatus used was an MA8-type high-pressure apparatus³, driven by the guide block/uniaxial press system of Nagoya University, and with a heating assembly similar to that described in ref. 4. The heating element used for the present experiments is a composite of tungsten carbide and diamond. The graphite sample capsule was placed between sheet heaters in the pressure medium, which is made of sintered magnesia containing 8 mol % CoO. A tungsten-rhenium (W25% Re-W3% Re) thermocouple, 0.2 mm in diameter, was placed in contact with the sample capsule, without making electrical contact with the heater. The furnace components and pressure medium were heated to ~1,000 °C for 1 h to remove water. The charge was dried again in an oven at 170 °C for a few hours immediately before the experiments.

The pressure was calibrated using the resistance changes associated with phase changes in Bi, Pb, ZnS and GaAs. A temperature correction was applied to the pressure values calibrated at room temperature, based on the phase boundary curves determined at pressures below 15 GPa by in situ X-ray diffraction experiments⁹. The resulting uncertainty in the pressure values was ± 0.6 GPa at 15 GPa and ± 2 GPa at 20 GPa.

The pressure was applied first, after which the temperature was increased to the desired value and held constant for ~2 min. The charge was quenched by turning off the electrical power to the furnace. The run products recovered after quenching were examined by X-ray powder diffraction, optical and scanning electron microscopy and electron probe microanalyser (EPMA) analysis. The melt is identified under the scanning electron microscope by the presence of fibrous or dendritic texture, which has been established as diagnostic of quenching from liquid at very high pressure^{3,4}.

The conditions and the results of the high-pressure runs are summarized in Fig. 1 as a phase diagram. The run made at 12 GPa and 1,900 °C indicated that olivine is the liquidus phase; thus, the partial melt formed at this pressure is richer in SiO₂ than the starting material with chondritic mantle composition. This result is consistent with melting experiments on the natural peridotite KLB1 (ref. 10). The sub-solidus mineralogy at this pressure is olivine, clinopyroxene and garnet. Figure 2a shows the back-scattered electron image of the charge adjacent to the thermocouple junction, quenched at 20 GPa and 2,050 °C. In this portion of the charge the liquid coexists with two phases; majorite and modified spinel. Figure 2b shows the highertemperature portion of the same charge, in which the quenched

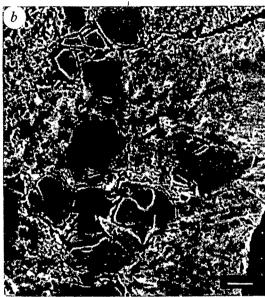

Fig. 2 Back-scattered electron images of the partially molten textures of the model chondritic mantle composition quenched at 20 GPa. In a, the quenched liquid (bright parts) is located in interstices between majorite (light grey crystals) and modified spinel (dark grey crystals). In b, the quenched liquid, now an aggregate of fine dendritic quench crystals, is coexisting with majorite (large grey crystals). Scale bars, 10 μm.

liquid coexists with granular majorite crystals as a liquidus phase. The temperature difference between the two portions of the charge should have been <100 °C, on the basis of a measurement of the temperature distribution in a similar furnace system¹¹. The sub-solidus mineralogy at 20 GPa is a mixture of majorite and modified spinel. Majorite was also observed as the liquidus phase at pressures of 15 and 17.5 GPa. The present experiments clearly demonstrate a change of the liquidus phase from olivine to majorite at a pressure between 12 and 15 GPa for the model chondritic mantle composition.

The compositions of minerals coexisting with a liquid, and of those observed under sub-solidus conditions (~1,930 °C), at 20 GPa were determined by EPMA and are given in Table 1. Note that the CaO/Al₂O₃ ratio of majorite above the solidus is lower than that observed under sub-solidus conditions; CaO and FeO contents of majorite decrease by partial melting. The partition coefficient K_D of Mg and Fe between majorite and

Ga I and MS I, majorite and modified spinel under sub-solidus conditions; Ga II and MS II, majorite and modified spinel coexisting with a liquid (Fig. 2a); Ga III and Liq III, majorite and coexisting liquid.

modified spinel is near unity at 20 GPa and >1,930 °C.

The composition of the liquid adjacent to majorite crystals in Fig. 2b was measured by EPMA with a diffused beam, ~15 µm in diameter. As the liquid could not be quenched to a glass (quench crystals of modified spinel, majorite and clinopyroxene were formed during quenching), the liquid composition (Table 1) was obtained by averaging measurements obtained over an area of >50 × 50 µm. The liquid is highly magnesian and peridotitic in composition. The FeO contents of the liquid and coexisting minerals shown in Table 1 are lower than would be expected from the starting composition; this is because some of the FeO was reduced to metal during heating at high pressure and temperature. (Small dispersed grains of metallic iron were observed in the charge.) The determination of the liquid composition has a large uncertainty, because of the heterogeneity of the aggregates of quench crystals formed from a liquid during quenching. Nevertheless, our result supports the generation of peridotitic magma by majorite fractionation at the base of a chondritic upper mantle. The low value of CaO/Al₂O₃ in the liquidus majorite implies that the partial melt has higher than chondritic CaO/Al₂O₃.

The partially molten zone may have extended to the deep upper mantle, or even to the lower mantle in the final stage of the accretion of the Earth^{1,2}. If the zone extended to the base of the upper mantle, the majorite fractionation and upward transportation of the peridotitic liquid could have produced a largely molten, peridotitic upper mantle 12-14, and a majoriteenriched transition zone. The upper mantle formed by the process would have a higher than chondritic CaO/Al₂O₃ ratio, as shown in the present experiment. Thus, the suggestion of Pulme and Nickel¹⁵ that the upper mantle has a high CaO/Al₂O₃ ratio, compared with the chondritic value, is consistent with an upper mantle chemistry derived from majorite fractionation by partial melting in the deep upper mantle.

Melting of garnet peridotite to 13 GPa and the early history of the upper mantle

Christopher M. Scarfe* & Eiichi Takahashi

Institute for Study of the Earth's Interior, Okayama University, Misasa, Tottori-Ken 682-02, Japan

By analogy with the evolution of the Moon, it has been suggested that the Earth may have had a 'magma ocean' or liquid outer layer before 3,800 Myr ago. 1. Its presence would have had profound implications for the primary stratification of the mantle into upper mantle, transition zone and lower mantle^{2,3}. An essential constraint on this hypothesis is a knowledge of the high-pressure melting characteristics of mantle material, generally assumed to be peridotite in the upper mantle. We recently described the first melting experiments on mantle peridotite to 14 GPa. Using spinel lherzolite KLB-1 from Kilbourne Hole, New Mexico, we showed that partial melts close to the solidus at 5-7 GPa are komatiitic in composition and that the solidus and liquidus converge at high pressures. Here we report further melting experiments on garnet lherzolite PHN1611 from Thaba Putsoa, Lesotho. We confirm the convergence of the solidus and liquidus and we show a negative dT/dP slope for the liquidus above 7 GPa. These observations are briefly discussed in terms of their importance to the petrological evolution of the upper mantle and the presence of a magma ocean in the early Archaean.

PHN1611 is a sheared garnet peridotite⁵. The bulk composition is given in Table 1 along with analyses of the constituent mineral phases. The composition (Mg/Mg+Fe=0.87; CaO/Al₂O₃=1.19) is close to pyrolite⁶ and is thought to represent undepleted or fertile mantle lherzolite⁷. The melting relationships of PHN 1611 at pressures ≤ 3.5 GPa have been previously reported, both for the anhydrous rock⁸⁻¹⁰ and in the presence of H₂O (ref. 9) and CO₂ (ref. 11).

Experimental methods and calibration procedures are similar to those in our previous report and are fully described elsewhere¹². The major technological innovation was the use of the 5,000-ton uniaxial, split-sphere, 6-8-type, multi-anvil apparatus developed by Ito^{13,14}. The apparatus incorporates a large sample volume and is capable of pressures of at least 30 GPa and temperatures >2,000 °C. Our experiments are the first melting studies on natural rock material using the split-sphere apparatus.

Figure 1 shows that at 1 atmosphere the temperature interval between the liquidus and solidus of PHN1611 is 500 °C: the solidus is at 1,125 °C, the liquidus at ~1,625 °C. With increasing pressure, however, at 5 GPa the solidus is at 1,700 °C and the liquidus at 1,975 °C. At still higher pressures the solidus increases more gradually, to 1,825 °C at 13 GPa. In contrast, at pressures >7 GPa the liquidus temperature no longer increases, but decreases to 1,900 °C at 13 GPa. The negative slope of the liquidus allows the liquidus and solidus to converge, until at 13 GPa the melting interval is <100 °C. In our previous study of KLB-1, results above 10 GPa suggested convergence of the solidus and liquidus, but the results were not definitive enough to confirm convergence⁴.

New determinations of the melting curve of diopside extend the results of Boyd and England¹⁵ from 5 to 13 GPa. Figure 2 shows the melting curve of diopside, along with the melting curves for forsterite¹⁶ and pyrope¹⁷. The diopside melting curve flattens at pressures between 7 and 13 GPa and varies little from 2,000 °C. This behaviour contrasts with that of the melting curve for forsterite, which approximates a straight line with a slope of dT/dP = 41 °C GPa⁻¹ (ref. 16). However, the curvature of the diopside curve is similar to the strong curvature shown by

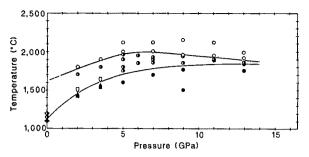

Fig. 1 Phase diagram showing the melting of garnet peridotite PHN1611 to 13 GPa. Experiments close to the liquidus were typically 1 min in duration; however, experiments close to the solidus and in the sub-solidus ranged from 10 to 150 min. Uncertainties in pressure and temperature are discussed in detail elsewhere 12. Because of possible hydration problems, all sample and pressure assemblies were heated with a propane torch before final assembly and were stored in an oven at 120 °C. O, Super-liquidus; O, crystals+liquid; sub-solidus. Open and filled arrowheads show solidus brackets from refs 8-10.

the melting curve for pyrope, which is attributed to a possible change in Al^{3+} in the melt from 4- to 6-coordination with oxygen¹⁷. Preliminary results by Ohtani and Irifune¹⁸ for diopside to 10 GPa also suggest a flattening of the melting curve at pressures >8 GPa. At 7-13 GPa, diopside melt does not quench to a glass but exhibits prismatic quench crystals. Note, on the other hand, that at \leq 5 GPa diopside melt can be quenched to a glass⁵. This could imply a change of melt structure above and below 7 GPa.

It is possible that the negative slope of the peridotite liquidus above 7 GPa is due to the solution of CO₂ or CO in the melt as a result of reduction of iron oxides in the charge by graphite from the graphite capsule. Carbon dioxide reduces melting temperatures at lower pressures 11,19; however, both the solidus and liquidus should be affected. Microprobe analyses of carbon in two charges (CMS 62, 13 GPa, 1,920 °C; CMS 52, 11 GPa, 1,900 °C) by T. Furuta (Ocean Research Institute, University of Tokyo) show concentrations of <0.5 wt % using Al metal as a conductive coating. At this stage, however, these analyses must be considered preliminary because no special precautions were used to exclude carbon during polishing of the charges and because the analyses involved the development of special techniques.

The compositions of melts and coexisting crystals have been reported for spinel lherzolite KLB-1 in our previous paper⁴. The results for PHN1611 are very similar and we report here only analyses of the composition of near-solidus olivine, clinopyroxene and garnet as a function of pressure (Table 1). The major point is that above ~ 5 GPa at temperatures ≥ 1.750 °C the near-solidus assemblage is olivine + clinopyroxene + garnet. Orthopyroxene was not identified and must be excluded at high pressures by solution of the enstatite component in both clinopyroxene and garnet (Fig. 3). When compared with the composition of the starting material, with increasing pressure the Si and Mg/Mg+Fe contents of the garnet increase and the Al content decreases. At the same time, the clinopyroxene becomes depleted in Al and Ca and enriched in Fe. These trends may be compared with previous work on the sub-solidus phase relationships of PHN 1611 (ref. 20), and on pyroxene-garnet solid solution relationships in Mg- and Fe-rich systems²¹ and in the system CaO-MgO-Al₂O₃-SiO₂ (CMAS; ref. 22). Note, however, that any differences may be accounted for by the much higher temperatures of the present experiments compared with temperatures of ≤1.500 °C in previous work. Recently, natural garnets from the upper mantle with pyroxene in solid solution have been described by Moore and Gurney23. These garnets, found as inclusions in diamond in kimberlite, have similar compositions to garnets in the experiments.

The present results for garnet lherzolite PHN1611 confirm our previous work on spinel lherzolite and show the convergence of the solidus and liquidus of mantle peridotite at pressures >7 GPa. This result had been anticipated by Herzberg²⁴. Below, we discuss three implications of the results.

First, the question arises as to whether complete convergence takes place between the liquidus and solidus at some pressure above 13 GPa, or whether the curves approach each other but do not actually join (see refs 24-28). In a multi-component system with solid solutions, complete convergence may not occur but a close approach is possible. Therefore, it is anticipated that at a pressure close to 15 GPa the slope of the liquidus will again become positive and a cusp or inflection will be generated where olivine is replaced by garnet-pyroxene solid solution (majorite)^{12,24}. At this cusp, for small temperature excursions across the solidus, melts would be close to the bulk composition of upper mantle peridotite.

Second, because of the negative $\mathrm{d}T/\mathrm{d}P$ slope of the liquidus, melts in equilibrium with olivine in the pressure interval 7-13 GPa may be denser than olivine, in order to satisfy the Clapeyron relationship. However, note that the Clapeyron relationship is strictly applicable only to systems where the liquid and solid compositions are identical; in a natural multi-

component system where liquids and coexisting crystals have different compositions, additional terms are required^{24,29,30}. Olivine flotation was not confirmed in our experiments, but we believe this may be due to the very short run durations near the liquidus and to the presence of temperature gradients in our charges¹². The possibility that melts at high degrees of partial melting are more dense than olivine has profound implications for melt-crystal dynamics at depth in the Earth. The most obvious conclusion is that melts, once formed at depths >200 km, may not be able to rise to shallower levels, but will remain concealed at depth. The density cross-over between liquid and crystals results from the greater compressibility of silicate melts at high pressure compared with their coexisting crystalline solids^{29,31}. Several petrogenetic possibilities related to this observation have been discussed elsewhere ^{12,24-27,29,31,32}.

Third, it has been suggested that the Earth may have possessed a liquid or partially molten 'magma ocean' during the early stages of its evolution 2,3,26,32 . A similar concept has been discussed in relation to the evolution of the Moon¹. Our present results suggest that because of the close approach of the solidus and liquidus at pressures of ~ 15 GPa, the Earth could have had a subterranean molten layer of broadly lherzolitic composition. Whether the eutectic-like melting behaviour implies that the

According to recent studies (F. R. Boyd, personal communication), PHN1611 may have been affected by metasomatism immediately before eruption; however, the magnitude of any compositional changes is unclear. Analyses of experimental charges were performed at Misasa with a JEOL JXA-5A microprobe. Conditions for wavelength-dispersive analysis were a 15-kV accelerating voltage, a beam current of 20 nA and counting times of 40-70 s. Data reduction using ZAF corrections. ND, Not determined.

upper mantle itself is a partial melt sweated out of the whole mantle^{26,27,33}, and whether on cooling and crystallization the layer would fractionate olivine by flotation and garnet solidsolution by settling^{2,3,26,27}, thus inducing some mineralogical stratification of the upper mantle, are questions that go beyond the scope of this paper. However, the melting phase relationships of garnet peridotite presented here provide a starting point for modelling the early Earth and the evolution of its upper mantle.

This study was supported by grants 58460042 and 59540525 from the Ministry of Education, Science and Culture of Japan. C.M.S. acknowledges the support and hospitality of ISEI and travel funds from Canadian NSERC grant IC-0214 and the University of Alberta Central Research Fund, Samples of PHN1611 were supplied by Drs F. R. Boyd and P. H. Nixon. We thank Dr E. Ito for advice and use of his apparatus. Comments by Drs D. L. Anderson, F. R. Boyd, C. T. Herzberg, E. Ito, Y. Matsui and D. Walker helped to improve the manuscript.

Evidence from the Parana of south Brazil for a continental contribution to Dupal basalts

C. J. Hawkesworth*, M. S. M. Mantovani†, P. N. Tavlor[‡] & Z. Palacz*

It has been suggested^{1,2} that the oceanic upper mantle preserves a large scale isotope anomaly, Dupal², which may be thousands of millions of years old. New Nd-, Pb- and Sr-isotope data on the continental volcanic rocks of the Parana, south Brazil, reveal 'enriched' isotopic ratios, with $^{87}\mathrm{Sr}/^{86}\mathrm{Sr} = 0.705-0.716$ and $\varepsilon_{\mathrm{Nd}} =$ -2.5 to -8, similar to those from other continental flood basalt provinces. Their ²⁰⁷Pb/²⁰⁴Pb ratios are higher than those of midocean-ridge basalts (MORB) at comparable ²⁰⁶Pb/²⁰⁴Pb, and even though the basalts appear to have been derived from lithospheric sources within the sub-continental mantle, they preserve isotope and trace element ratios similar to those in oceanic basalts with the Dupal signature in the South Atlantic. The implied link between these continental flood basalts and Dupal oceanic volcanics raises the possibility that in some areas the Dupal anomaly marks a comparatively shallow-level feature in the Earth's mantle.

The Parana is one of the largest known continental flood basalt provinces (106 km²). Most age determinations cluster around 130-120 Myr (ref. 3), so that the Parana appears to be contemporaneous with the Etendeka volcanics in Namibia and the opening of the South Atlantic⁵. The Parana rocks range from tholeiitic basalts to rhyodacites and rhyolites. The more evolved rocks tend to occur at higher stratigraphical levels, and in a large regional study by Bellieni et al.⁶ they comprised ~16% of the rocks analysed.

Geochemically the Parana volcanics consist of two apparently discrete groups characterized by different minor and trace ele-

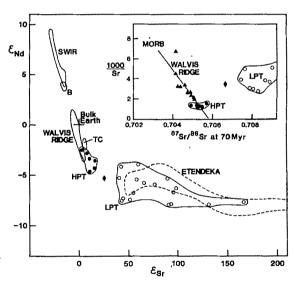

Fig. 1 Plot of $\varepsilon_{\rm Sr}$ versus $\varepsilon_{\rm Nd}$, comparing Parana data with those from: SWIR, south-west Indian Ridge; B, Bouvet; TC, Tristan da Cunha, the Walvis Ridge, and the low-Ti Etendeka rocks from Namibia 12,22,26,27. ●, HPT; ○, LPT; ◆, a transitional basalt. Inset, 1,000/Sr versus ⁸⁷Sr/⁸⁶Sr for the Walvis Ridge (A) and Parana rocks (after ref. 22).

ment abundances and 87Sr/86 ratios6-9. The HPT (high phosphorus and titanium) rocks have high P2O5, TiO2, Sr and LREE (light rare-earth element) contents but, at least in the samples analysed here, restricted major element contents (SiO₂= 49.3-53.9%, MgO = 5.0-4.3%) and initial 87Sr/86Sr (0.7048-0.7058). LTP (low phosphorus and titanium) rocks exhibit a full range from basalt to rhyolite, but have low P₂O₅ and TiO₂ (<0.3 and 2.0%, respectively), and high and variable initial 87Sr/86Sr (0.7076-0.7160). Mantovani et al.8 explained the striking increase in 87Sr/86Sr with differentiation in the LPT rocks in terms of crustal assimilation during high-level fractional crystallization (AFC). However, they and others⁶⁻⁹ have argued that the HPT and LPT series were derived from sources with different minor and trace element features, and probably different 87 Sr/ 86 Sr, of ≈ 0.705 and ≈ 0.707 respectively.

Regional studies of the Parana have demonstrated that, as in

* Data from ref. 8 except for Sm and Nd results with three significant figures, which are by isotope dilution.

† Measured ratios. Analytical errors = 0.007% for ${}^{87}Sr/{}^{86}Sr$ and 0.11% for Pb. ${}^{87}Sr/{}^{86}Sr$ in NBS987 = 0.71018 ± 4 and ${}^{143}Nd/{}^{144}Nd$ in BCR-1 = 0.51262 ± 2 . Pb isotope ratios corrected for -0.1%/AMU mass fractionation, assessed from repeated analysis of NBS 981.

the Karoo¹⁰⁻¹¹, the northern rocks are predominantly high-Ti, whereas those in the south are low-Ti (ref. 10). Our samples, for which fuller descriptions are given elsewhere⁸, are from close to the probable boundary between high- and low-Ti provinces⁹. Most are from a detailed section at 28 °S, in which high-Ti rocks are confined to a 200-m segment (30%) near the base.

All samples have higher $^{87}\text{Sr}/^{86}\text{Sr}$ and lower $^{143}\text{Nd}/^{144}\text{Nd}$ ratios than the bulk Earth (Table 1). HPT rocks show restricted ε_{Sr} (from 4 to 16) and ε_{Nd} (from -2.5 to -4.6), and plot on an extension of the so-called mantle array (Fig. 1). The LPT rocks have slightly lower ε_{Nd} (from -3.7 to -7.9), but higher and more variable ε_{Sr} , plotting in a flat-lying field on the ε_{Nd} - ε_{Sr} diagram similar to that for contemporaneous lavas in Namibia which are also low-Ti (refs 11-13).

Pb isotope data for the Parana define arrays sub-parallel to MORB, but displaced to higher $^{207}\text{Pb}/^{204}\text{Pb}$ and $^{208}\text{Pb}/^{204}\text{Pb}$ (Fig. 2). The slope of the array in the $^{207}\text{Pb}/^{204}\text{Pb}-^{206}\text{Pb}/^{204}\text{Pb}$ diagram corresponds to an apparent age of $\sim 2,000$ Myr, and the array yields a single-stage model μ value of 8.11. The Pb isotopes straddle the first-stage geochron for 120 Myr (the best estimate of eruption age), with the HPT rocks generally having less radiogenic Pb ($^{206}\text{Pb}/^{204}\text{Pb}$ from 17.06 to 17.73) than the LPT (Fig. 2).

Crustal contamination is a possibility during continental magmatism^{14,15}. For the Parana, the present consensus is that the HPT exhibit no clear signs of significant contamination⁶⁻⁹. They evolved in an environment characterized by high Ti, Ta and Sr abundances, and with trace element ratios similar to OIB (ocean island basalts), presumably in the sub-continental mantle. In contrast, the striking changes in isotope ratios with SiO₂ in the LPT are due to open-system differentiation within the crust, and determination of the isotope ratios of uncontaminated LPT remains problematical. Published models emphasize that primitive HPT and LPT magmas had different isotope and trace element ratios, perhaps with $\varepsilon_{\rm Sr} = 30$ -40 (and by implication from Pb-Sr correlations, $^{206}{\rm Pb}/^{204}{\rm Pb} = 18$) in uncontaminated LPT

On the ²⁰⁷Pb/²⁰⁴Pb-²⁰⁶Pb/²⁰⁴Pb diagram the HPT and LPT

data lie on sub-parallel, slightly en echelon, trends (Fig. 2). The LPT field is dominated by progressive contamination, with more radiogenic Pb in the higher SiO₂ rocks. The HPT rocks, which show no evidence of crustal contamination, plot approximately on the extension of the LPT trend at less radiogenic compositions, and define an apparent isochron age of 1,800 ± 400 Myr (MSWD=0.7), with a model μ value of 8.1. This age is very similar to a Pb-Pb age of $2,180 \pm 180 \,\mathrm{Myr}$ (model $\mu = 8.06$) recently reported by Mantovani et al.16 for nine composite samples of basement rocks from beneath the Parana, and the simplest interpretation is that the major crust-forming event in this area took place ~2,200 Myr ago, and that in the following 200-300 Myr mantle material stabilized within the continental lithosphere. Such material probably included mantle depleted after crust extraction, and variably enriched by trapped melts and fluids. It was later remobilized in the Parana event, and from the initial isotope ratios of the HPT rocks, it had average U/Pb=0.08, Sm/Nd=0.27 and Rb/Sr=0.049. Comparison with measured trace element ratios in the HPT indicates that in this model Sm/Nd was on average reduced by 18%, and Rb/Sr increased by 8%, during melting and subsequent fractionation.

Coupled crust-mantle domains have been invoked elsewhere ^{13,17,18}, but the question is whether material from the continental lithosphere subsequently contributes to the composition of the oceanic basalts ^{19,20}.

Hart's recent survey of isotopic data from both oceanic and rift-related continental basalts indicated that, while many scatter around a Pb/Pb array that includes most MORB, there are areas where the basalts are consistently displaced to relatively high $^{207}\text{Pb}/^{204}\text{Pb}$ and $^{208}\text{Pb}/^{204}\text{Pb}^2$ (ref. 2). Termed the Dupal anomaly, one such area is in the South Atlantic (Fig. 3), where rocks with $\Delta7/4>10$ and $\Delta8/4>100$ tend also to have high $^{87}\text{Sr}/^{86}\text{Sr}$, ($\Delta\text{Sr}>45$). The relation between Pb and Sr isotopes is complex, and although the relatively high- $^{207}\text{Pb}/^{204}\text{Pb}$ rocks tend to have higher $^{87}\text{Sr}/^{86}\text{Sr}$, there is no simple correlation between $^{87}\text{Sr}/^{86}\text{Sr}$ and $^{206}\text{Pb}/^{204}\text{Pb}$ along the Pb/Pb arrays.

Variations in 207 Pb/ 204 Pb and 208 Pb/ 204 Pb require long-lived variations in U/Pb and Th/Pb (>10⁹ yr), but they may be

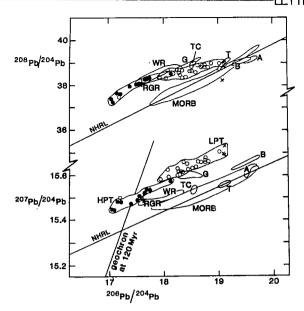

Fig. 2 Pb-isotope diagrams. Parana symbols as in Fig. 1. NHRL, the Northern Hemisphere Reference Line from ref. 3. RGR, Rio Grande Rise; WR, Walvis Ridge; TC, Tristan de Cunha; G, Gough; T, Trinidad; A, Ascension, B, Bouvet^{22,28}

interpreted as evidence either for old, anomalous regions in the sub-lithospheric mantle, or for the introduction of anomalous Pb from lithospheric reservoirs. Hart² preferred the former because recent injection of crustal material would tend to generate Pb/Pb arrays at a high angle to the MORB trend, rather than sub-parallel to it. Weaver et al.21 demonstrated that in the South Atlantic, basalts from the area of the Dupal anomaly are characterized by higher La/Nb, Th/Ta, Th/U, Ba/La and Ba/Nb than basalts from outside the anomaly. Such high ratios are relatively unusual in OIB and were attributed by Weaver et al. to the introduction of a few per cent of pelagic sediment. In contrast, Richardson et al.22 suggested that a similar component in the Walvis Ridge basalts was derived from enriched (metasomatized) material comparable to that proposed for the continental lithosphere.

A feature of the Dupal anomaly in the South Atlantic is that it appears to be restricted to an area between those of continental volcanism associated with continental break-up, Parana and Etendeka (Fig. 3). Moreover, both the HPT and the more primitive LTP rocks have the relatively high ⁸⁷Sr/⁸⁶Sr and ²⁰⁷Pb/²⁰⁴Pb ratios which define the Dupal anomaly in oceanic areas. LTP rocks, however, have minor and trace element features markedly different from OIB (for example, low Ti), which precludes any simple relation between the LPT rocks and oceanic magmatism (see also Fig. 1 inset). By contrast, the HPT rocks have many similarities with OIB.

For all three isotope systems, and for 1/Sr-87Sr/86Sr, it is remarkable that the HPT Parana rocks plot at the end of the Walvis Ridge trend (Figs 1 and 2). In addition, the HPT lie at the high-Ba/Nb end of a striking positive correlation between Ba/Nb and $\Delta 7/4$ for South Atlantic basalts in the Dupal area²³. Thus, HPT rocks were either derived from source regions similar to the enriched component invoked for the Walvis Ridge, or they at least contain more of that component. This component has distinctive low ²⁰⁶Pb/²⁰⁴Pb, similar to that inferred for portions of the sub-continental mantle from studies of lamproites and mantle xenoliths 24,25

The Dupal signature has been identified in ocean islands such as Gough and Tristan da Cunha, on the Walvis Ridge², and in the HPT rocks of the Parana. It has been suggested that it was derived from either enriched lithosphere²², or recycled sediments²¹, but since both probably reflect subduction processes they may prove difficult to distinguish.

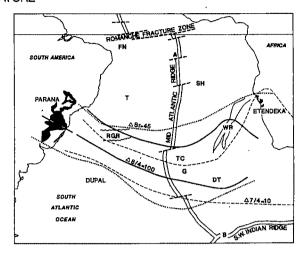

Fig. 3 Sketch map of Dupal anomaly isotope contours in the South Atlantic, after ref. 2. $\Delta 7/4$ and $\Delta 8/4$ are measures of the deviation of individual Pb isotope analyses from the NHRL, (Fig. 2). $\Delta 7/4 = [^{207}\text{Pb}/^{204}\text{Pb}_s - ^{207}\text{Pb}/^{204}\text{Pb}_{\text{NHRL}}]100; \Delta 8/4 \text{ is calculated similarly, but } \Delta \text{Sr} = [^{87}\text{Sr}/^{86}\text{Sr}_s - 0.7]10^4.$

The presence of Dupal features in both oceanic and continental flood basalts, and their apparent restriction in the South Atlantic to areas between the Etendeka and the Parana, implies a close link between continental and oceanic magmatism. One interpretation is that the Dupal geochemistry is due to a deepseated upwelling³ that both initiated continental break-up and was responsible for the Dupal signature. However, that requires that the trace element and isotope characteristics of the Karoo and Parana basalts are from deep-seated sources, rather than from within the continental lithosphere as presently believed^{4,10,11}, and it would conflict with suggestions that the mantle sources of both Karoo and Parana basalts are locally of similar age to the overlying crust 12,12,16. An alternative interpretation is that, at least in the South Atlantic, the Dupal is a relatively shallow-level phenomenon which evolved in the continental lithosphere. In this model, the Dupal signature occurs between the areas of continental volcanism because in those areas lithospheric mantle had been significantly heated and remobilized before continental break-up. Remobilization of such material detaches it from the lithospheric plates and hence enables it to contribute to oceanic volcanism as the continents move apart and the ocean basin develops.

We thank Peter van Calsteren, Andrew Gledhill and Roy Goodwin for help with the isotope analyses, and Peter van Calsteren and Nick Rogers for comments on the manuscript. Borming Jahn and Jon Patchett provided thoughtful reviews. Travel grants for M.M. were provided by FAPESP, the British Council and CNPq, and for this work the laboratories at the Open University and Oxford were supported by NERC.

Acidity of Scottish rainfall influenced by climatic change

T. D. Davies*, P. M. Kelly†, P. Brimblecombe*, G. Farmer† & R. J. Barthelmie†

* School of Environmental Sciences, and † Climatic Research Unit, School of Environmental Sciences, University of East Anglia, Norwich NR47TJ, UK

Although there are clear links between acidic deposition and synoptic meteorology¹, the effects of climatic change have been largely neglected. It is demonstrated here that long-term variations in the atmospheric circulation and associated changes in trajectory characteristics on timescales of years and longer can affect deposition levels within the United Kingdom, masking the effects of changing emissions. This study provides empirical support for the suggestion that climatic change may need to be considered in the assessment of emission control strategies2.

The potential importance of climatic change in influencing precipitation acidity has been acknowledged3-6 but not assessed, although significant changes in climate and the atmospheric circulation have occurred in the European area over the past 100 yr (refs 7-9). As the frequency and character of air trajectories between regions varies, the relative importance of different source regions for deposition in a particular area will alter. Moreover, other physical and chemical processes in the atmosphere which influence deposition may also be affected. The spatial pattern of deposition over Europe as a whole could alter and climatic change may explain the apparent disagreement between recent trends in European pollutant emissions and precipitation composition 10,11.

Here, we consider the link between recent fluctuations in precipitation acidity (H+ concentration) at Eskdalemuir in Scotland (Fig. 1) and variations in the frequency of various atmospheric circulation types over the United Kingdom extracted from the Lamb Catalogue of Daily Weather Types¹². This catalogue provides a succinct characterization of the synoptic circulation and extends back to 1861 enabling the study of long-term trends. On an annual basis, three Lamb Weather Types (LWTs) account for much of the variance in the circulation over the United Kingdom: Westerly (W); Anticyclonic (A); and Cyclonic (C)8. A-types produce little rainfall although they may be of ultimate importance for acidic deposition¹. C- and W-types together produce ~50% of the precipitation in the UK; no other type accounts for more than ~10%.

We have undertaken trajectory analyses for the C- and Wtypes to determine their significance for acidic deposition at Eskdalemuir. The synoptic situation characterized by the Ctype¹² is such that, when there is frontal precipitation over Scotland, back-trajectories often originate over England or adjacent continental Europe (work in preparation). This is likely to lead to relatively acidic precipitation over Scotland 13,14. W-types. on the other hand, are more commonly associated with maritime trajectories and less-polluted rainfall in Scotland¹³. Variation in

Fig. 1 Location of precipitation-collecting station used in this study: E, Eskdalemuir. The shaded areas represent major pollution sources, H+ concentration data available for this station include: a, bulk-monthly, 1958-78 (Meteorological Office); b, daily, 1973-77 (Warren Spring Laboratory), c, daily, November 1977 to September 1982 (EMEP), same collector as b. Further details are available elsewhere 14,20

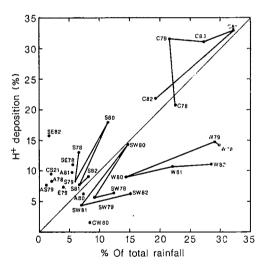

Fig. 2 Relationship between Lamb Weather Type, percentage of total H+ deposition and precipitation amount at Eskdalemuir (annual values derived from EMEP daily data). Only LWTs contributing >7.5% of annual H⁺ deposition and >7.5% of annual precipitation have been included. For clarity, the points for the major LWT contributors have been joined. The acid content of annual precipitation is dominated by C-type and W-type events. C-type events account for about 30% of the total H⁺deposition and around 25% of the total rainfall; the respective values for W-type events are ~12% and 25%. Although other LWTs make significant contributions to the concentration or dilution of precipitation acidity in certain years (S-type and SE-type events in particular), the acid content of annual precipitation is dominated by C- and W-type associated rainfall. C-type events make the major contribution of all LWTs to concentrating H+ levels (a large average departure in the +y direction from the equality line combined with a substantial contribution to the total rainfall) whereas W-type rainfall makes the major contribution to diluting H+ levels (greatest departure in the -y direction from the equality line along with a large contribution to the annual rainfall). C, Cyclonic; CS, cyclonic-southerly; CW, cyclonic-westerly; W, westerly; A, anticyclonic; S, southerly; SE, southeasterly; SW, southwesterly; E, easterly.

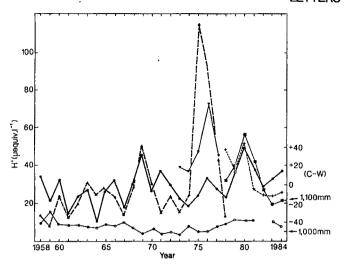

Fig. 3 Annual values of the C-W index, rainfall total for Eskdalemuir and volume-weighted H⁺ concentration data for Eskdalemuir (for sources, see Fig. 1). The average H⁺ concentration for seven collectors distributed through Scotland is also shown (data provided by J. N. Cape). The reliability of the monthly bulk collector data should be viewed with extreme caution²⁰. Unfortunately, they represent the only long-term records of precipitation acidity for the UK. Bottom curve, annual rainfall (mm); ▲ and dashed line, Eskdalemuir monthly H⁺; ▼ and light solid line, Eskdalemuir daily H⁺; ■ EMEP daily H⁺; ● and heavy solid line, C-W; + and dotted line, Scotland regional H⁺.

wind speed between these types may also affect precipitation acidity¹³, as may other characteristics of the weather types. On the basis of our analysis of trajectories associated with the two LWTs, we conclude that these indicators of the general state of the local circulation can be used as a surrogate for case-related trajectory analysis; an expedient which allows us to explore the historical dimension of acidic deposition.

Analysis of the daily EMEP precipitation composition data¹⁴ for Eskdalemuir for the period January 1978 to October 1982 shows the prevalence of C-types in acidic episodes¹. These episodes, periods of high deposition on the day-to-day timescale, were first ranked according to order of magnitude. Then, the LWTs associated with the largest episodes each year (in total accounting for one-third of the total H⁺ deposition in that year) were identified. The resulting frequency of C-types (~10 events per year) was four to five times that of the nearest contenders, the S-type (Southerly) and the W-type.

In determining the significance of the individual weather types for total H⁺ deposition, precipitation amount is also important. Figure 2 illustrates the relationship between H⁺ deposition, precipitation amount and LWT. C-type events account for between 20 and 25% of total H⁺ deposition; W-types for 10-15%. C-type rainfall is high and relatively acid; W-type rainfall is similar in amount but lower in acidity. A simple index of the influence of atmospheric circulation variation on H⁺ deposition can, therefore, be devised by subtracting the number of W-type days from the number of C-type days (the C-W index). This should be related to volume-weighted H⁺ concentration in precipitation. More complex indices which included other LWTs and weighting to account for relative importance were devised but did not differ substantially in terms of information content from the C-W index.

Figure 3 shows the annual C-W index for the period 1958-84 during which rainfall H⁺ concentration observations for Eskdalemuir are available. Despite problems with the reliability of the earlier acidity data, the overall relationship between these variables is clear, confirming that shifts in the atmospheric circulation do play a part in the determination of deposition

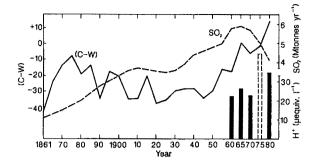

Fig. 4 Five-year means for: the C-W index (1861-64, 1865-69, and so on); SO_2 emissions estimated from published data²² (the data must be considered notional before 1950); and 5-yr volume-weighted H⁺ concentrations at Eskdalemuir using the Meteorological Office bulk monthly data and the EMEP daily data. In the latter case, the pentade 1975-79 is represented differently to highlight: the anomalous nature of the 1975-76 period; and the use of two different data sources during this interval.

levels in the Eskdalemuir region.

The relationship breaks down in certain years: for example, 1971 and, most notably, 1975 and 1976. The period of greatest acidity during the latter years, June 1975 to July 1976, was coincident with a severe drought over England and Wales¹⁵⁻¹⁷. Frontal depressions were steered further north over the UK than usual and, although there was a drought in the South, Scotland received between 70 and 110% of its 'normal' rainfall. Synoptic patterns which are recognized to produce acidic episodes frequently affected Scotland. Ozone concentrations were also high over the UK during this period¹⁸ and this may have influenced sulphate production¹⁹ and led to greater rainfall acidity, further complicating the situation.

The C-type count for the 1975-76 period was low and, in this case, the simple C-W index was not a good measure of the atmospheric factors affecting production, transport and deposition. A more sophisticated index may be needed. Nevertheless, the correlation between the annual C-W index and the H⁺ concentration data for the period 1958-84 is statistically significant. A correlation analysis yields a coefficient of 0.38, significant at the 5% level (the coefficient is 0.59 if the years of 1975 and 1976 are excluded). The relationship between these variables cannot be stationary in time because of changes in other important factors such as varying emissions. A more appropriate measure of association may, therefore, be a sign test on the year-to-year fluctuations. In this case, the test statistic is significant at the 0.1% level (data were included for all years during the period 1958-84).

Figure 4 shows the long-term history of the C-W index. Allowing for the anomaly in the mid-1970s, the 5-yr volume-weighted H⁺ concentrations at Eskdalemuir show a closer match with this record than with that of UK emissions of SO₂. (Sulphate has been the anion best correlated with precipitation acidity in Scotland²⁰.) Besides the strong relationship on the year-to-year timescale, there may also be a link on longer timescales. Unfortunately, the H⁺ record is too short to test this point statistically

This association between climatic change and precipitation acidity in the UK shows that the climate dimension must be taken into account in any consideration of the acid rain issue. Our index could be criticised on the grounds of oversimplicity and further work is needed to determine whether other indicators are more appropriate. Nevertheless, this analysis demonstrates that, as climate changes, deposition levels can vary even in the absence of alterations in emissions. As well as compounding the problem of assessing emission control strategies², this complicates the determination of the effects of past emissions. Climatic change may produce biological damage in its own right

or in conjunction with pollutants²¹, and it may also exert an indirect influence via its contribution to acidic deposition variability.

This work is funded by the UK Department of Environment and the Commission of the European Community. We thank Dr J. N. Cape (Institute of Terrestrial Ecology), Mr A. Martin (Central Electricity Generating Board), Dr J. G. Irwin (Warren Spring Laboratory) and Dr A F. Tuck (Meteorological Office) for helpful advice and for permission to use their data. We also thank Dr F. B. Smith (Meteorological Office) and Dr B. E. A. Fisher (CEGB) for their valuable comments. The Norwegian Institute for Air Research was particularly helpful with the provision of data as were the Central Electricity Research Laboratories.

Simultaneous outflow of fresh water and inflow of sea water in a coastal spring

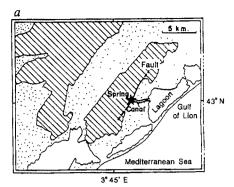

Claude Drogue & Pascal Bidaux

Laboratoire d'Hydrogéologie, Université des Sciences et Techniques, Place E. Bataillon, 34060 Montpellier Cedex, France

The ability of sea water to flow into coastal or submarine cavities is surprising, in view of the fact that sea level is, for water, a level of minimum gravitational potential where it can perform no work. To achieve a lower potential requires energy, the provision of which is an example of a completely original aspect of the interaction between subterranean hydrodynamics and marine hydraulics. We have studied a spectacular example of the simultaneous outflow of fresh water and inflow of salt water at a karstic spring running into a salt-water lagoon on the French Mediterranean coast, and we suggest here a hypothesis to account for the surprising doublelayered, two-directional flow observed.

The flow of sea water into cavities is known to occur in, among other places, the Bahamas, Florida and Greece, where limestone which is in contact with the sea displays considerable karst development and is very permeable. There appear to be various causes-proved or supposed-for the inflow of sea water¹⁻⁵; the examples described in the literature are continuous or periodic but consist of either inflow of sea water or outflow of fresh water. The two types of flow never occur simultaneously.

The work described here reveals the possibility of a more complex coastal phenomenon in which two flows-outflow and

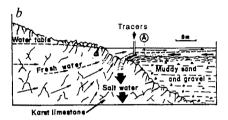

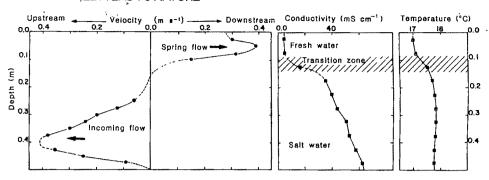

Fig. 1 a, Map showing the location of the Source de la Roubine. The carbonate massif has an area of 55 km² and consists of Mesozoic limestone and dolomite. It is only part of the aquifer feeding the spring; other massifs located further north also contribute to the supply. The deposits of Quaternary and Cenozoic clay, loam and sand in the plain are several hundred metres thick and cover Mesozoic limestone which extends beneath the sea. The level of the Mediterranean has undergone a number of fluctuations since the end of the Neogene, and during some periods was lower than it is today¹⁰⁻¹³. These regressions caused deep penetration by rainfall infiltrating into the carbonate massifs which had emerged, accompanied by intense internal corrosion and the formation of cavities by dissolution (karst topography). Thus, the aquiferous structure which formed in the depths of the carbonate mass is mainly below sea level today, and the Source de la Roubine is a spring of very recent formation. Movement of water starts in the form of a rising current in the deep palaeokarst. b, Cross-section of the spring showing the double flow (vertical exaggeration 5:1). Tracers were injected into the stream of salt water through a pipe, as shown in the drawing. Measurements of velocity, conductivity and temperature were made along the vertical marked 'A'.

inflow—are concomitant and superposed. The study was carried out at a spring on the Mediterranean coast (Source de la Roubine, Fig. 1a), which is at the edge of an extremely karstic carbonate massif and quaternary clay-marl deposits several hundred metres thick in the coastal plain. The spring and flow run along a 2.5-km channel into a lagoon (sea water). The discharge can attain a value of 6 m³ s⁻¹, and is 0.1-0.2 m³ s⁻¹ at normal low-water functioning of the spring, that is, when the spring is flowing. Inflow of salt water occurs only during such times of low discharge⁶.

In the absence of rain, rises of several tens of centimetres are observed in the water level near the spring and last from a few hours to 4-5 days. While the water level changes in this way, a current of salt water runs along the bottom of the channel below the fresh water and in the opposite direction, enters one or two of the springs and disappears into the aquifer. At the same time, water continues to run out of the other springs and flows towards the lagoon on top of the salt water (Fig. 1b).

The interface between the two flows can be clearly seen in vertical profiles of electrical conductivity and temperature. (Fig. 2). The conductivity of the water from the spring is 4.2-4.3 mS cm⁻¹ (at 25 °C), whereas that of the lagoon water varies from 48 to 56 mS cm⁻¹ according to the season. Although for reasons of convenience the spring water is referred to as 'fresh', the mean electrical conductivity of spring water in limestone soil far from the coast is 0.6 mS cm⁻¹ with a Cl⁻ ion content of

Fig. 2 Observations of velocity, conductivity and temperature, showing the superposition of the two streams. Maximum velocities of the two currents running in opposite directions are almost the same. The discharge of the fresh-water stream is 0.18 m³ s⁻¹; that of the salt-water stream beneath is 0.20 m³ s⁻¹. The superposition of fresh water is also shown by the observations of conductivity and temperature. The lagoon water is warmer than the spring water.

 $15-35 \text{ mg l}^{-1}$ (the water in the lagoon has a Cl⁻ content of $18,000 \text{ mg l}^{-1}$).

The temperature of the spring is relatively stable, at 17.3 ± 0.5 °C. In contrast, the lagoon water is subject to wide temperature variations: from 5-10 °C in winter to 25-28 °C in summer. The monitoring of inflow with time revealed some remarkable features. The beginning of the double-flow phenomenon has a sudden effect on conductivity values: this is proof of the poor miscibility of fresh and salt water. The temperature, however, varies progressively even before the appearance of salt water. This is caused by the fact that the advance of the salt water in the bottom of the channel pushes the fresh spring water already affected by the outside temperature back towards the spring.

With regard to the hydraulic mechanism, it would appear that the variations in the water level at the spring are caused by variations in the level of the lagoon on the west bank. The measurements (Fig. 3) show that they are not caused by tide;

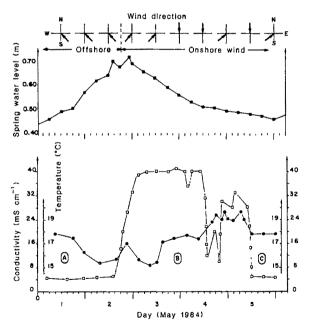

Fig. 3 Example of the time-evolution of conductivity (□) and temperature (●) in the spring into which the salt water flows, compared with water levels in the spring (■) and with wind direction (arrows). A, No inflow of salt water, but start of return flow is indicated by a fall in temperature. This is fresh water in the channel affected by the outside temperature. B, Inflow has started suddenly and is revealed by stable conductivity; however, temperatures are irregular. This is the effect of the thermal heterogeneity of the water in the lagoon. The lowest temperature of the water flowing in is 14.9 °C; the highest is 19.8 °C (the temperature of the spring water is 17.8 °C). C, Inflow ceases suddenly. The spring flows normally once more. Inflow occurs when there is a rise in water level of 0.35 m caused by easterly winds.

however, it was observed that the variations are associated with certain wind directions. The spring is on the west bank; easterly winds cause the water level to rise on this side and fall on the east bank. The rapid rise in level on the western side thus sets up a hydraulic gradient in the salt water, directed towards the spring. Progress of salt water towards the spring is encouraged by the low hydraulic gradient of the fresh water in the channel ($\sim 0.01\%$) and by the near-zero slope of the bottom of the channel.

The superposition of the two flows and the low apparent miscilibity of the two streams are caused by the differences in density (spring water: 0.9994 kg dm⁻³ at 25 °C; sea water (in the lagoon): 1.0258 kg dm⁻³).

Finally, it might be thought that the salt water which runs into the aquifer reappears in spring flow after dilution and could be the cause of the salinity of the spring. Tracers were injected into the saline inflow in order to test this hypothesis, and no trace of the dye was observed in fresh water to the spring during an observation period which lasted several months. It would thus appear that the two flows are probably separate in the aquifer itself.

It is likely that part of the salt water mixes with water from the aquifer, but the origin of most of the salinity of the spring water is undoubtedly contamination of deep ground water by the penetration of sea water into the karst⁷⁻⁹ (salt-water encroachment; Fig. 4). When lagoon water has flowed in, it probably runs by gravity to the interface of the salt-water encroachment. It may then be taken by groundwater flow to springs under the lagoon or under the sea.

In conclusion, we note that geological structures which could

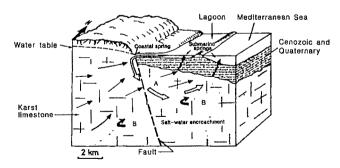

Fig. 4 Diagrammatic representation of the karstic aquifer and the organization of flows. Fine arrows, fresh water; bold and shaded arrows, salt water. The flow of salt water that runs into the spring must descend by gravity through the aquifer (A) to the deep salt-water encroachment (B). This flow is then carried to submarine springs. There is thus double contamination of underground water by sea water: from below in the aquifer and from above. Note that the large-scale flow of water into the spring carries large quantities of organic matter into the underground zone; this could form the basis for a totally unknown biotope. (For reasons of simplicity, the arrows in A do not show any dispersion that may take place in the aquifer.)

enable this phenomenon to occur are very common on the limestone coasts around the Mediterranean. Equivalent structures also exist on ocean coasts: we have observed such features in Miocene limestone in south-east Java (Gunung Sowu) and in southern Portugal (Algarve).

Sign language aphasia during left-hemisphere Amytal injection

Antonio Damasio*, Ursula Bellugi†‡, Hanna Damasio*, Howard Poizner† & John Van Gilder*

Although it has been established that the left cerebral hemisphere subserves spoken language, the nature of brain organization for sign language remains relatively unexplored. The issue is especially important because sign language displays the complex linguistic structure of spoken languages, but conveys it through manipulation of visuo-spatial relations1, thereby exhibiting properties for which the hemispheres of hearing individuals show opposing specializations. We had the unique opportunity to study a hearing signer proficient in American sign language (ASL), during the left intracarotid injection of a barbiturate (the Wada test), and before and after a right temporal lobectomy. The subject was a strong righthander. Neuropsychological and anatomical asymmetries suggested left cerebral dominance for auditory-based language. Emission tomography revealed lateralized activity of left Broca's and Wernicke's regions for spoken language. The Wada test, during which all left language areas were rendered inoperative, caused a marked aphasia in both English and ASL. After partial ablation of the right temporal lobe, the abilities to sign and understand signing were unchanged. These data add further support to the notion that anatomical structures of the left cerebral hemisphere subserve language in a visuo-spatial as well as an auditory mode.

Recent research has shown that ASL has developed as a fully autonomous language. It has complex organizational properties shared by the spoken languages of the world, but it also has grammatical devices not derived from spoken language; thus, ASL is a separate language, not a manual rendering of English. At all structural levels, the surface forms of a signed language are deeply influenced by the modality in which it develops. This is displayed most distinctively in the pervasive use of spatial contrasts and spatial manipulations to express syntactic function. At the syntactic level, for example, nouns are associated with arbitrary points in signing space, pronoun signs are directed toward those points for anaphoric reference, and verb signs move between them in specifying grammatical relations². Thus a grammatical function served in many spoken languages by case marking or by linear ordering of words is fulfilled in ASL by essentially spatial mechanisms. Since sign languages utilize visuo-spatial channels, several investigators have assumed that structures in the right cerebral hemisphere are likely to have a major role in the reception and production of these languages. Indeed, the issue is quite controversial and many studies do suggest a special role for the right hemisphere in mediating signs³.

Our study was performed in a 27-yr-old hearing woman, a native English speaker who learned ASL at an age of 18 yr. She is a college graduate with a MS degree in rehabilitation of the deaf, and works at a community agency as interpreter and counsellor for deaf people. She uses ASL daily in her work and is a skilled signer. She had her first seizure, of the partial complex type, at age 13 yr, but had never had generalized tonic-clonic seizures. The seizures did not hamper her intellectual or emotional development, but in recent years the episodes had become more frequent and refractory to drug therapy. Because they were interfering with her professional activity she sought surgical treatment. She is a right-hander (in Geschwind's version of Oldfield's laterality index, she scored +90), and so are both her parents. Comprehensive neuropsychological evaluation failed to reveal any abnormality of language, visuo-spatial or other higher cognitive abilities. Her full-scale intelligence quotient (Wechsler Adult Intelligence Scale-Revised) was 105, with no discrepancy between the verbal and performance scales. Her dichotic listening performance for words showed a right-ear advantage. Computer tomographic scan and cerebral angiography revealed brain asymmetries suggestive of left language dominance (left>right occipital width on computer tomography; left sylvian angle = 105°; right sylvian angle = 130°, in angiography). Recording from depth electrodes showed a right anterior temporal focus. There was no mirror focus.

Single photon emission tomography (SPET) using xenon-133 as radiotracer revealed a normal resting pattern⁴. A second SPET procedure was performed during a language activation task, a verbal rhyme detection paradigm modified from Knopman⁵. The subject compared words presented through earphones with a memorized target word and was asked to respond with left foot flexion to those words that rhymed with the memorized target. SPET revealed increased signal in the left Broca and Wernicke regions (see Fig. 1), indicating that processing of English was lateralized to the left.

Injection of a barbiturate (sodium amobarbital; Amytal) was made into the left carotid system (due to a persistent right trigeminal artery, no injection was possible in the right side). The procedure was videotaped and both English and ASL examiners were in attendance. The patient developed a right hemiplegia and aphasia in both English and ASL. During the recovery period, correct English responses appeared at 4 min, preceding those in ASL by $1\frac{1}{2}$ min, a substantial time interval in this procedure. The patient's signing was markedly impaired, including sign paraphasias, perseverations, neologisms and grammatical errors. Interestingly, since she was hearing and could sign and speak at the same time, we could compare her responses in two languages simultaneously. This revealed a frequent mismatch between word and sign, with English mostly correct but ASL often incorrect in both meaning and form (see Fig. 2).

The extent of the surgical resection was documented by postoperative advanced magnetic resonance imaging (see Fig. 3). It encompassed the right hippocampus, parahippocampal gyrus, amygdala and both polar and anterolateral right temporal neocortex. The primary and secondary auditory association cortices contained in the middle and posterior first temporal gyrus were spared, as was area 37.

Neuropsychological re-evaluation at 3 and 12 months comprised all the tests administered pre-operatively, to assess attention, perception, language, memory and reasoning. The scores were virtually unchanged, including those of the Boston Diagnostic Aphasia Examination⁶, dichotic listening, recognition and recall of previously learned visual stimuli, geographical orienta-

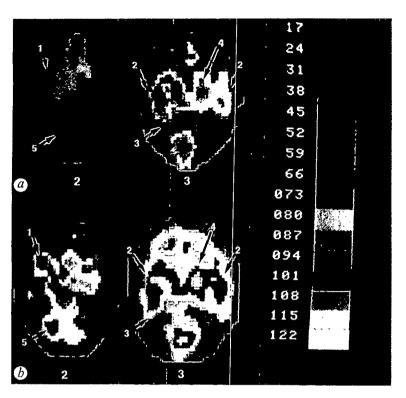

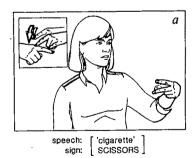

Fig. 1 Cuts 2 and 3 of a six-slice Tomomatic SPET study at rest (a) and during a verbal rhyme detection task (b). During activation there is an increase of radiosignal in Broca's region, that is, in the left frontal fields 44 and 45 indicated by arrow 1, and a bilateral increase of signal in auditory cortices indicated by arrow 2. In the left hemisphere the signal increase extends into Wernicke's area, that is, the posterior sector of area 22 (arrow 3). During activation there is also an increase in the right basal ganglia (arrow 4) and left cerebellar hemisphere (arrow 5), related to the motor activity of the left foot required to signal appropriate rhyme detection.

tion, immediate visual memory (Benton's visual retention test), and copy and 15-min recall of a visual pattern (Rey-Osterrieth figure). The learning of new visuo-spatial and visual object memories was not assessed. There were no detectable neurological abnormalities. Most importantly, however, analysis of videotaped spontaneous signing and structured signing interviews confirmed the patient's own impression that her ability to sign and understand signing had not been compromised at all. Intensive analysis of her videotaped signing showed, for example, that her noun to pronoun ratio was in the normal range, her use of ASL morphological structures was unchanged, and there were no errors in her use of the spatially organized syntax of ASL before or after the right temporal lobectomy.

The impairment of ASL during the Wada test is associated with pharmacologically induced dysfunction in the territory of

the left middle and anterior cerebral arteries⁷. The structures clearly affected during the test included the left Broca and Wernicke areas, the left dorsolateral parietal lobe (especially the inferior parietal lobule), the middle and lower rolandic cortices, the left basal ganglia and possibly territories of both the lateral temporal lobe and the anterolateral frontal lobe⁸. The cerebral territories supplied by the left posterior cerebral artery (namely, the mesial and part of the lateral occipital lobe, and the mesial occipito-temporal and occipito-parietal regions) were probably unaffected. This indicates that a fully operational right hemisphere and partially operational, interconnected, left visual cortices could not prevent the impairment in sign language. Thus ASL may be especially dependent on the normal function of left hemisphere cortices, as is the case with auditory-based languages.

b a second secon

speech: ['orange' sign: [Neologism] ORANGE/SCISSORS blend

Speech: ['cat'].
Sign: [Neologism].
different ORANGE/SCISSORS blend

Fig. 2 Three errors produced by the patient during left Wada injection. In identifying an object presented, the patient produced an English word and an ASL sign simultaneously, and the two differed. In a, the patient correctly said 'cigarette' but simultaneously signed 'scissors' to a presented cigarette. In b, the patient correctly said 'orange' to a presented orange, but signed a form that was like a blend of two signs in ASL—the handshape of 'orange' and the place and movement of 'scissors'. In c, the patient correctly said 'cat' to a picture of a cat, but signed another blend, this time with the handshape of 'scissors', the place of articulation of 'orange' and the movement of 'scissors'. The combinations of parameters from different signs produced nonsense forms that were well-formed in ASL but were meaningless. It is of interest that during recovery from the left Wada injection, the patient frequently responded in speech and sign simultaneously-a unique possibility for languages in different modalities—with a mismatch between the two languages and the sign more often in error. Inserts in the upper left-hand corner of the

illustrations indicate the correct ASL signs.

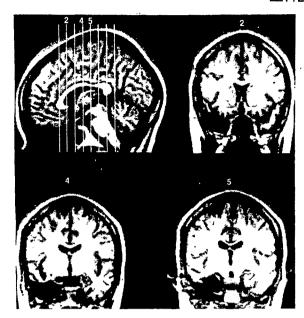

Fig. 3 Magnetic resonance images obtained after surgery with an inversion recovery technique; magnetic field, 0.5 T. Resolution was 2 mm in the plane of cut. The top left-hand image is a midsagital cut showing the mesial aspect of one hemisphere. The vertical lines represent the level and incidence of the coronal cuts. Cuts 2, 4 and 5 are reproduced depicting the area of right temporal lobe ablation. Hippocampus, parahippocampal gyrus, fourth, third and second temporal gyri are missing. The first (superior) temporal gyrus is intact.

A major point of interest concerns the rate of recovery of the languages. During the final period of dysfunction, after the use of English had returned and the paralysis subsided, the patient still made errors in ASL. Considering that the recovery from barbiturate action must have taken place gradually and have occurred last in the outer border of the middle cerebral artery territory, that is, in a C-shaped watershed region containing visual and somatosensory cortices that we believe are especially crucial for ASL processing, it is possible that the ASL delay reflected the continued dysfunction of those cortices at a time when the core territories of the middle cerebral artery (which contain the classic speech cortices) had already returned to normal. An alternative explanation for this lag would need to invoke the fact that ASL was a second language and propose that its neural representation might thus be more vulnerable, a rather unsatisfactory hypothesis. In fact, one might have expected a second language, and especially a visuo-spatial language, to have been primarily represented in the non-English dominant hemisphere, in which case the left Wada test would not have interfered with ASL operations at all.

The lack of post-operative signing defects suggests that right anterior temporal structures medially and laterally do not have a significant role in signing or in comprehension of previously learned signs. It is possible that these areas are pertinent to the learning of ASL but certainly not to the production of ASL once learned, that is, the right hippocampal/parahippocampal complex and the polar and anterolateral temporal cortices were involved in neither the generation nor the detection of the complex visuo-spatial and motor patterns of ASL that had been learned pre-operatively. It might be argued that this patient's seizure would have so disorganized the structure of the right hemisphere that any ability normally dependent on it would have been transferred to the healthy left hemisphere. This possibility is unlikely considering: (1) the mild and circumscribed neuropathological changes encountered in the block of ablated tissue; (2) the lack of a mirror focus in the opposite hemisphere; (3) the lack of any pre-operative symptom or sign suggestive of right hemisphere dysfunction; (4) the late onset of the seizures; and (5) the fact that they never interfered with the acquisition of skills or the development of a normal personality.

Our findings provide the rare opportunity of relating the processing of ASL to a circumscribed set of brain structures in the left hemisphere, in a subject who has unequivocal left-sided functional dominance for English, and who has anatomical brain asymmetries also favouring the left hemisphere. Furthermore, the findings suggest that the right hippocampal system is not involved in active processing of ASL. Our results should be seen in the perspective of other converging evidence on the respective roles of left and right hemisphere in ASL⁹⁻¹¹. Studies of unilateral lesions in deaf signers show that lesions to the left hemisphere cause sign aphasia, affecting different structural levels of the language, while lesions to the right hemisphere produce marked spatial deficits but leave expressive language intact12. Thus, the underlying specialization of the left hemisphere for language does not seem to rest on speech or sound. nor on the form of the signal, but rather on the linguistic function

We thank Dr Paul Eslinger for performing the neuropsychological assessment, Drs Karim Rezai and Val Dunn for their collaboration in the SPET and magnetic resonance imaging studies, Mr Ozzie Diaz-Duque and Ms Charissa Lansing for their assistance with sign language procedures during the Wada test and David Corina, Maureen O'Grady, Lucinda O'Grady and Diane Lillo-Martin for their help with the sign language analysis. This research was supported in part by NINCDS grant PO NS 19632-02 (to A.D. and H.D.), NSF grant BNS 83-09680 and NIH grants HD13249, NS15175, NS19096 (to U.B. and H.P.).

Electrokinetic shape changes of cochlear outer hair cells

Bechara Kachar*, William E. Brownell†, Richard Altschuler‡ & Jörgen Fex‡

Laboratories of * Neurobiology and ‡ Neuro-Otolaryngology, NINCDS, National Institutes of Health, Bethesda, Maryland 20892, USA

Departments of Neuroscience and Surgery (ENT), Box J-244, University of Florida, Gainesville, Florida 32610, USA

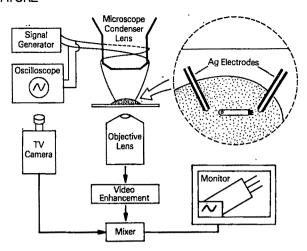

Rapid mechanical changes have been associated with electrical activity in a variety of non-muscle excitable cells¹⁻⁵. Recently, mechanical changes have been reported in cochlear hair cells⁶⁻⁶ Here we describe electrically evoked mechanical changes in isolated cochlear outer hair cells (OHCs) with characteristics which suggest that direct electrokinetic phenomena are implicated in the response. OHCs make up one of two mechanosensitive hair cell populations in the mammalian cochlea; their role may be to modulate the micromechanical properties of the hearing organ through mechanical feedback mechanisms⁶⁻¹⁰. In the experiments described here, we applied sinusoidally modulated electrical potentials across isolated OHCs; this produced oscillatory elongation and shortening of the cells and oscillatory displacements of intracellular organelles. The movements were a function of the direction and strength of the electrical field, were inversely related to the ionic concentration of the medium, and occurred in the presence of metabolic uncouplers. The cylindrical shape of the OHCs and the presence of a system of membranes within the cytoplasm—laminated cisternae¹¹—may provide the anatomical substrate for electrokinetic phenomena such as electrosmosis^{12,13}.

Isolated OHCs were prepared from the organ of Corti of guinea pig by non-enzymatic mechanical dissociation^{7,8}. A 100-µl volume of culture medium containing isolated cells was placed on a microscope slide and viewed with video-enhanced microscopy (Fig. 1). Isolated OHCs attach to the microscope slide at either the synaptic or the stereociliar end. Sinusoidal potential gradients at 2-30 Hz and <1 mA (0.8-1.5 V peak-topeak) were passed across OHCs by means of a pair of silver-wire electrodes placed 200-300 µm apart (Fig. 1). About 100 isolated OHCs from 34 cochleae were analysed from experiments recorded on videotape.

Oscillatory movement of the cell's free end, corresponding to elongation and shortening of the cell in response to the electrical stimulation, was visualized in over 80% of the OHCs. Oscillatory movement of intracellular organelles located around the cell axis was observed in ~15% of the OHCs. Maximal responses of up to 0.3-0.4 µm amplitude about a resting position (Figs 2, 3) were obtained when the cells were longitudinally aligned with the direction of the electrical field. We could not distinguish oscillatory movements from brownian movement for amplitudes smaller than 50 nm. Most OHCs showed elongation with positive potential gradients and shortening with negative potential gradients, when the ground electrode was placed near the end of the cell that was attached to the substrate (Figs $2\dot{a}-d$, 3a,b,d). Less than 20% of the OHCs showed the opposite response polarity. Organelle movement, when detectable in cells that also responded with length changes, was in-phase with the movement of the free end of the cell (Fig. 3d,e). Organelle movement was also observed in some cases when both the stereociliar and synaptic ends were attached to the slide. Oscillatory movements of organelles or changes in cell length were not observed in red blood cells, Deiters' or Hensen's cells which co-isolate with the OHCs.

These electrically evoked responses persisted for several hours after dissociation. The responses were unchanged when the cells were incubated for 1 h in medium containing dinitrophenol (2 mM) or iodoacetic acid (2 mM), both of which are inhibitors of ATP production and commonly used to test for energy requirements^{14,15}. The responses were enhanced by lowering the ionic concentration by 20–25% (this was achieved by isotonic dilution of the medium with a sucrose solution). Some cells showed little or no movement in the standard medium but exhibited robust movement after ionic dilution; this effect was reversed by replacing the diluted medium with the original medium (Fig. 3 d).

The symmetry of the sinusoidal displacements, their apparent independence of ATP involvement, and the enhanced responses after ionic dilution are difficult to reconcile with conventional contractile mechanisms. However, electrophoresis ^{13,16} and electro-osmosis ^{12,13} might provide the motive force underlying both the length changes and the oscillatory organelle movements. Such electrokinetic phenomena are a function of applied voltage and are enhanced in medium of low ionic concentration ^{12,17}. Electro-osmosis is a field-induced movement of fluid adjacent to a charged surface as a consequence of the electrophoretic migration of counterions ^{12,13,17-19}. When electro-osmosis occurs in a tube with closed ends, a pressure difference develops between the tube ends ¹⁹. If the tube wall is elastic it can deform (elongate or shorten), or if it is rigid the flow of liquid along

Schematic diagram of the video-enhanced light microscopy³¹ system used in the present experiments. An inverted Zeiss Axiomat was operated in the differential interference contrast mode and equipped with a ×100, 1.3-NA Planapo objective, a 0.63-NA condenser fully illuminated with a 100-W mercury lamp and a Newvicon Dage-68 (MTI) video camera for contrast enhancement. The magnification of the image on the TV monitor was ×20,000. Experiments were carried out in droplets of medium (Leibovitz L-15 with 1% bovine serum albumin and 10 mM HEPES). A droplet containing cells was placed on a microscope slide which had been pretreated with polylysine. Isolated OHCs in most cases adhere to the slide surface at either the basal (synaptic) of apical (stereociliar) region. Stimulation was achieved with a pair of Teflon-insulated no. 30 silver-wire electrodes placed 200-300 µm apart and mounted on the microscope condenser lens. The electrode pair was lowered into the droplet and oriented in relation to individual OHCs by rotating the microscope stage. The voltage waveform was displayed on an oscilloscope screen and the video image mixed with that of the video-enhanced image of the OHC. The response of the cells to electrical stimulation were analysed by frame-by-frame playback of videotape-recorded experiments. Time resolution was limited to 17 ms, corresponding to the duration of a single non-interlaced video frame. Photographs and measurements were taken from a TV monitor.

the wall is counterbalanced by a flow in the opposite direction at the centre of the tube¹⁸.

OHCs display structural features that are favourable for electrokinetic effects. OHCs are elongated cylinders, 4-9 µm wide and 15-70 µm long, and they contain parallel membranes that form the laminated cisternae along the lateral plasma membrane¹¹ (Fig. 2f). The function of the cisternae is unknown. The closely apposed membranes may be an optimal substrate for an electro-osmotic effect¹². Cytoplasmic fluid movement in relation to the plasma and cisternal membranes would produce pressure variations and changes in cell shape.

Evidence that bulk fluid oscillatory movement is induced by potential gradients is provided by the fact that all organelles in the axial region of the cytoplasm move in concert and to an equal extent, not with different amplitudes as expected for an inhomogeneous population of organelles with different electrophoretic mobilities. In addition, free cytoplasmic organelles from disrupted cells fail to respond to the same electrical gradients.

It is unknown why different OHCs show different polarity of the displacement responses. Structural and metabolic differences between OHCs isolated from different turns or different rows in the cochlear spiral^{20,21} may alter the balance of forces resulting from the electro-osmotic fluid drag and the electrophoresis of soluble metabolites¹⁶ as well as of components of the membrane¹³ and of the cytoskeleton.

The requirement of video enhancement to visualize the shape changes and the intracellular organelle movements limited our

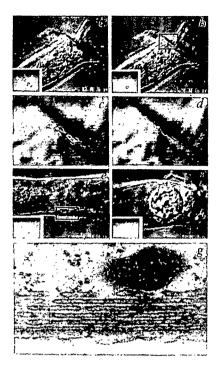

Fig. 2 Mechanical responses of OHCs to transcellular stimulation. a, Video-enhanced image of the stereociliar end of an OHC at the positive phase of a sinusoidal stimulus (oscilloscope screen shown at lower left); the active electrode lies outside the field of view to the right, the ground electrode is positioned near the synaptic end of the cell to the left of the field of view. The time is indicated at the lower right. b, Image of the same cell as in a during the negative phase of the stimulus. c, d, Higher magnification of the images enclosed by the rectangle at the stereociliar end of OHC shown in a and b respectively; the lower arrow in c indicates a reference point in the screen with fixed coordinates, the upper arrow indicates the edge of the cell image. The OHC was longer during the positive phase (a and c) of the stimulus and shorter during the negative phase (b and d). e, f, Images of the middle (e) and synaptic end (f) of another cell; cytoplasmic organelles are clearly visualized. g, Thin-section electron micrograph from a region of OHC equivalent to that outlined by the rectangle in e, showing the laminated cisternal system adjacent and parallel to the plasma membrane. This system is found between the cuticular plate and the nucleus. There are 6-8 cisternae in guinea pig OHCs; the outermost layer is parallel to and 30-35 nm from the lateral plasma membrane and each layer is parallel to its neighbours and separated from the next layer by 15-20 nm¹¹. Magnifications: a, b, e, f, $\times 1,500$; c, d, $\times 7,500$; g, $\times 40,000$.

ability to resolve cycle-by-cycle changes beyond 30 Hz. However, we were able to see vibration and blurring of the image of OHCs in response to electrical stimulation above 100 Hz. In addition, Ashmore and Brownell²², reproducing our experimental conditions but using a linear position detector, recorded changes in cell length in response to stimulations in excess of 8 kHz.

OHCs in situ have no attachments at the lateral surfaces except for synaptic contacts at the base of the cell and an apical band of tight junctions with Deiters' cells in the reticular lamina. This tight junction constrains current flow in vivo; its absence in vitro would lead to current shunting around the cell. Therefore, the actual potential gradients driving the motile process in our experiments may approach the physiological values²³ (7 V m⁻¹) measured near OHCs in vivo. Furthermore, smaller physiological potential gradients would produce smaller displacements which would be more compatible with observed magnitudes of vibrations of the cochlear partition—of the order of angstroms at the threshold of hearing. The free lateral surfaces of OHCs permit free expression of length changes which in turn

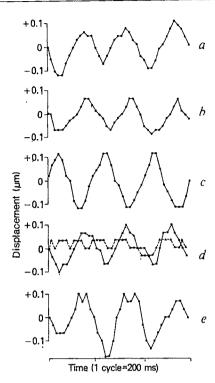

Fig. 3 Displacement evoked by 5-Hz sinusoidal transcellular stimulation, a-d. Plots of movement of the free end of OHCs: e is a plot of organelle movement. a, Apical end movement (same cell as in Fig. 2a-d), b. Basal end movement (same cell as in Fig. 2f). c, Example of free end movement of opposite polarity to that shown in a and b. d, Circles represent free end movements at reduced ionic concentration; triangles represent movements of the same cell under the same stimulus conditions, but using the original medium. We assume that a decrease in extracellular ionic strength leads to a decrease in the intracellular ionic strength; in support of this assumption are the findings of low resting potentials and input impedances of OHCs in vitro^{7,32}, consistent with a highly permeable plasma membrane. e, Organelle movement in the same cell as d under conditions of reduced ionic concentration; the response sinusoid is less regular because of concurrent brownian motion of the organelles.

affects the micromechanics of the cochlear partition^{7,24}. A change in the OHC length will change the separation between the reticular lamina and the basilar membrane and affect cochlear transduction^{7-10,25-27}. There is evidence that the efferent olivocochlear synapses on OHCs may modify the microm-echanics of the latter^{27,28,33}. In addition, electrical potentials (cochlear microphonics)²⁹ that vary at acoustic frequencies are generated by mechano-electrical transduction associated with the OHCs³⁰, which increases the significance of an electrokinetic basis for OHC length changes by permitting shape changes in the audio-frequency ranges.

We thank Remy Pujol for the electron micrograph shown in Fig. 2g. This research was supported in part by research grants BNS-12174 from NSF(USA), NS-19050 from NINCDS and a research stipend from INSERM (France) to W.E.B.

Ionic basis of membrane potential in outer hair cells of guinea pig cochlea

J. F. Ashmore & R. W. Meech

Department of Physiology, The Medical School, University of Bristol, University Walk, Bristol BS8 1TD, UK

Mammalian hearing involves features not found in other species, for example, the separation of sound frequencies depends on an active control of the cochlear mechanics1,2. The force-generating component in the cochlea is likely to be the outer hair cell (OHC), one of the two types of sensory cell through which current is gated by mechano-electrical transducer channels sited on the apical surface3. Outer hair cells isolated in vitro have been shown to be motile^{4,5} and capable of generating forces at acoustic frequencies⁶. The OHC membrane is not, however, electrically tuned, as found in lower vertebrates⁷⁻⁹. Here we describe how the OHC resting potential is determined by a Ca²⁺-activated K⁺ conductance^{10,11} at the base of the cell. Two channel types with unitary sizes of 240 and 45 pS underlie this Ca2+-activated K+ conductance and we suggest that their activity is determined by a Ca2+ influx through the apical transducer channel, as demonstrated in other hair cells 12. This coupled system simultaneously explains the large OHC resting potentials observed in vivo 13,14 and indicates how the current gated by the transducer may be maximized to generate the forces required in cochlear micromechanics.

Outer hair cells were isolated from the guinea pig cochlea and maintained in vitro at room temperature with no obvious change in their morphology for about 4 h (Fig. 1A; see also Fig. 1 legend). Their input conductance and resting potential, measured using whole-cell recording techniques¹⁵, were found to depend on the contents of the recording pipette. When the pipette contained 140 mM K⁺, the input conductance ranged from 25 to 40 nS (Fig. 1B, a). Typical resting potentials were -15 to -40 mV and only exceptionally were more negative. Comparable results were obtained with conventional high-resistance micropipettes (J.F.A., unpublished). Cells equilibrated with pipettes containing 140 mM Na⁺ had a lower input conductance $(2.9\pm0.9 \text{ nS } (\pm \text{s.d.}), n=6; \text{ Fig. } 1B, b)$. A low input conductance (4.8 nS) was also obtained with pipettes containing 100 mM CsCl. There was no significant difference in input conductance when the external Cl was replaced by gluconate. We conclude that under our experimental conditions the hair cell membrane is relatively impermeable to Cl⁻ and is more permeable to K+ than to Na+ by a factor of at least 5. Furthermore, hair cells in vivo have input conductances of $\geq 20 \text{ nS}^{16}$; thus, the values reported here suggest that the isolation procedure introduces little change in membrane leakage.

In some experiments with 140 mM Na⁺ in the recording pipette, depolarizing current pulses elicited what appeared to be a slowly developing active response (Fig. 1B, b). Such responses were not seen when the pipette contained 140 mM K⁺ (Fig. 1B, a) unless it also contained the Ca²⁺ buffer BAPTA¹⁷ (Fig. 1B,c). With 10 mM BAPTA in the recording pipette. intracellular levels of calcium would be expected to fall below 10⁻⁸ M. Thus the observed decrease in input conductance is consistent with a membrane K⁺ conductance gated by internal Ca²⁺ (ref. 18). Cells loaded with BAPTA and 140 mM K⁺ from the pipette had a final mean resting potential of -60 mV (n = 7)after equilibration (2-3 min), even though the initial resting potential was close to -10 mV. We attribute the increase in resting potential to a rise in internal K+ and the contribution of a small (<3 nS at -60 mV) residual K⁺ conductance.

When BAPTA-containing cells were studied under voltage clamp, step changes in membrane potential produced a large capacitive transient followed by a steady inward current (with hyperpolarizing pulses) or a slowly developing outward current (with depolarizing pulses; Fig. 2A). Both inward and outward currents were reduced or blocked by externally applied Cd²⁻¹ which blocks Ca2+ currents in many different tissues19 (Fig. 2B, c).

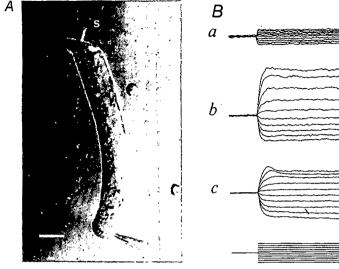

The residual ionic currents in saline containing 1 mM Cd2+ appeared to be largely time-independent; they were smaller in the outward direction than in the inward direction (Fig. 2B. C) but this anomalous rectification was not characterized further. In Fig. 2D, currents recorded in Cd²⁺ have been subtracted from those recorded in normal saline to show the Cd2+-sensitive fraction. The Cd2+-sensitive current makes only a minor contribution to the total membrane conductance (1-4 nS at -60 mV): it appears even at membrane potentials more negative than -100 mV, that is, beyond the normal operating range for Ca²⁺ channels, and is unlikely to be the remains of the Ca²⁺-activated K⁺ conductance because it appears even in cells containing 50 mM BAPTA. We propose, instead, that it crosses the membrane via the transducer pathway which, in other vertebrate hair cells, is known to be closed by Ca2+-channel blockers12

A prominent component of the Cd²⁺-sensitive current is apparent during membrane depolarization as a slowly developing outward current; this appears even in cells containing 50 mM BAPTA and its tail-current, seen when the membrane is repolarized, reverses at $\sim -50 \text{ mV}$ (not shown) and so it too may be associated with the transducer channel. However, H⁺ conductances appear in this voltage range in some cells and they are also blocked by Cd²⁺ (refs 20, 21). A rapidly developing Cd²⁺sensitive Ca2+-activated K+ current has been reported in isolated hair cells from the sacculus of the bullfrog⁷ but its time-course and voltage-dependence do not correspond to the Cd²⁺-sensitive currents reported here.

Single-channel recordings revealed several distinct channel populations which underlie some of the conductances observed in whole cells. In the cell-attached mode²² at least two populations were evident: an uncharacterized voltage-dependent channel with a unit conductance of ~30 pS, and a range of larger conductance channels (40-65 pS) subsequently identified as two populations of Ca²⁺-activated K⁺ channel. Unitary K⁺ currents recorded from such cell-attached membrane patches reversed direction at potentials between -20 and -30 mV, which is consistent with decreased levels of internal K+ in isolated cells.

Current records from single Ca2+-activated K+ channels were obtained with inside-out patches of membrane²³ taken from the basolateral region of the outer hair cells. One type of channel had a unit conductance of 233 ± 33 pS (n = 10) when bathed bilaterally in 140 mM KCl (Fig. 3A). This type of channel resembles the large-conductance Ca^{2+} -activated K^+ channel described in a variety of other systems²⁴⁻³¹ because its probability of opening increased with elevated Ca2+ at the internal membrane surface (Fig. 3C).

In addition to the large-conductance channel, a second class

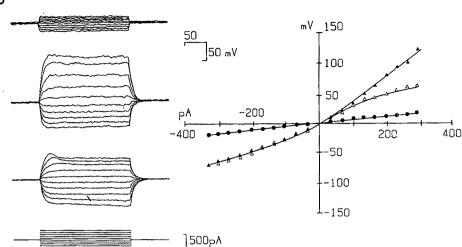

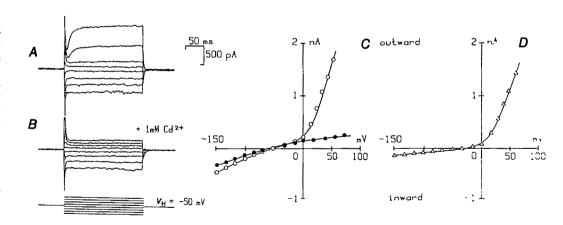

Fig. 1 Membrane permeability of isolated outer hair cells. A, An isolated outer hair cell of the guinea pig cochlea. The cell length indicates that the cell originates from the low-frequency end of the cochlea. The mechano-electrical transducer and stereocilia (s) on the apical surface face endolymph when in situ. Patch recordings were made on the basal surface as shown. Scale bar, 10 µm. B, Effect of different internal ions on membrane conductance of outer hair cells. The figure shows the changes in voltage observed during step changes in current, obtained in the whole-cell recording mode¹⁵ when the membrane potential had reached a steady level, that is, after 1-3 min (separate experiments with fluorescent dyes suggest that this corresponds to the time required for the cell contents to reach a steady state). The pipette contained: a, KCl, 140 mM, MgCl₂, 2 mM, 6.5×10^{-8} M Ca²⁺ (using 500 μ M EGTA/Ca²⁺ buffer), HEPES 5 mM; pH 7.6. Cell resting potential -29 mV. b, Same as in a except that NaCl replaced KCl. Cell resting potential +17 mV. In some cells depolarizing current pulses elicited a small, slowly developing active response on the rising phase of the trace. c, Same as in a except that 10 mM BAPTA (BDH) replaced the EGTA/Ca² buffer in the pipette. Cell resting potential -63 mV. C, Steady-state current/voltage curves obtained from the data in B. O, Data from a; A, data from b; \triangle , data from c. Zero on the voltage axis corresponds to the resting potential. Data were corrected for series resistance of the pipette (20-45 M Ω) in each cell.

Methods. Guinea pigs (300-500 g) were killed by rapid cervical dislocation, and their cochlear coils dissected out into L-15 medium (Gibco) using a fine needle. The apical two turns only were used; they yielded outer hair cells which were 55-80 µm long and had an electrical capacitance in whole-cell clamp of 24-32 pF. Each coil was removed into a 140-µl aliquot of medium containing 0.3 mg ml⁻¹ trypsin (Sigma type III S) for 30 min. The cells were mechanically dissociated and the volume increased to 300 µl in the microscope chamber. The major ions in L-15 medium are Na⁺ (145 mM), K⁺ (5.4 mM), Mg²⁺ (1.8 mM), Ca²⁺ (1.26 mM), Cl⁻ (147 mM) and phosphate buffer. Cells were observed under 40 × WI DIC optics. Patch recordings were made from the basal part of the cell using an EPC-5 amplifier (List Electronic). Pipettes were pulled on a two-stage puller, (BB-CH, Mecanex) and used without further treatment. Seal resistances >2 GΩ were obtained before whole-cell recording. Experiments were performed at room temperature (19-21 °C).

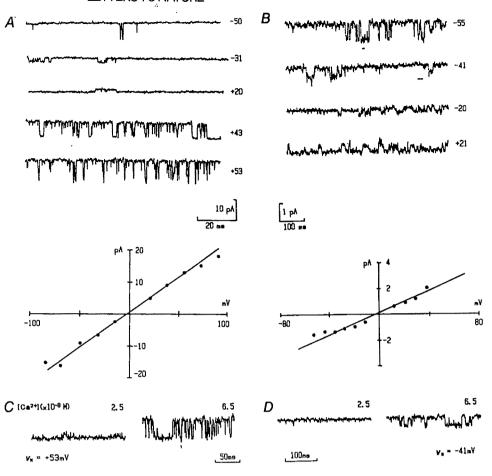

Fig. 2 Cd2+-sensitive K+ conductance in outer hair cells recorded under voltage clamp. The pipette was filled as for Fig. (10 mM BAPTA included). No cancellation of the capacitive transients was made; time constant 1.7 ms. Holding potential $(V_H) = -50 \text{ mV}.$ Step increment, 34 mV. A, 5 min after whole-cell recording conditions had been established. B, After addition of 1 mM Cd2+ to the bath. C, Currentvoltage curves showing:

O, steady currents during depolarizing or hyperpolarizing pulses in normal saline (data from A); •, steady currents in 1 mM Cd²⁺ (data from B). D, Cd²⁺-sensitive currents obtained by subtraction of Cd²⁺-resistant currents from currents observed in normal saline. The pipette series resistance (38 M Ω) measured in the bath was used to compensate C and D. Maximum slope conductance in A was 32 nS.

of Ca^{2+} -activated K^+ channel was found (Fig. 3B,D) which had a smaller single unit conductance, 44 ± 17 pS (n=6), when bathed bilaterally in 140 mM KCl. Ca²⁺-activated K⁺ channels with comparable conductances (25-92 pS in 140 mM K⁺) have been described in other vertebrate tissues^{27,32}. Like the largeconductance channel, this channel 'turned on' at Ca²⁺ levels between 2.5×10^{-8} and 6.5×10^{-8} M (with EGTA buffer, pH 7.6) but its kinetics were less complex. We have investigated the possibility that it was a fragment of some other channel. We found that membrane patches generally had either large- or small-conductance channels and at no time did we observe large-conductance channels decomposing into smaller ones. The selectivity of the two Ca²⁺-gated channels for K⁺ over Na⁺ was about the same; the reversal potential shifted by 35-55 mV per 10-fold reduction of K⁺ at the inside surface. In these experiments we found that Na+ at the internal surface of the membrane produced a 'flickery' block of both types of K^+ channel at positive membrane potentials^{31,33,34}.

Fig. 3 Ca²⁺-activated K⁺ currents in outer hair cells. Single channels recorded from inside-out patches. A, Large-conductance Ca²⁺-activated K+ channels observed at different patch potentials, as indicated; inward current downwards. The channel open probability increased with depolarization of the intracellular surface of the isolated patch (~30 mV for an e-fold change). The pipette contained (in mM): 140 KCl, 1.25 CaCl₂, 2 MgCl₂, 5 HEPES pH 7.4; the cytoplasmic face was bathed in 140 mM KCl, 6.5×10^{-8} M Ca²⁺ (500 μM EGTA/Ca²⁺ buffer), 2 mM MgCl₂, 5 mM HEPES pH 7.6. In bilateral 140 mM KCl, the unit slope conductance was 220 pS, measured from well-resolved openings. The K/Na permeability of this channel, determined by altering K+ at the cytoplasmic surface, was ~7:1. Recording bandwidth (via 4pole Bessel filter) 1.6 kHz. B, Small-conductance Ca²⁺-activated K⁺ channel observed under the same conditions as in A. Unit slope conductance 45 pS. Recording bandwidth 880 Hz. Large-conductance (C) and small-conductance (D) channel types are activated by levels of Ca2+ at their intracellular surface that are greater than 2.5×10^{-8} M. Values shown alongside each record show the prevailing Ca2+ concentration (in µM) at the cytoplasmic sur-

face; this was changed using a continuous flow system³⁸. The holding potential $V_{\rm H}$ (+53 mV for large-conductance channel; -41 mV for small-conductance channel) was the same for both Ca²⁺ solutions. In 2.5×10⁻⁸ M Ca²⁺ the channels were generally inactive at voltages between -70 and +70 mV. EGTA buffers were used throughout.

In summary, we have been able to convert isolated outer hair cells with a high input conductance and low resting potential into cells with a resting potential near normal; we have done this by introducing the Ca2+ buffer BAPTA into the cell interior and by raising the level of internal K⁺. We have also identified two populations of channels which underlie this resting Ca²⁺activated K⁺ conductance. In vivo the transducing surface of an outer hair cell faces a K⁺-rich endolymph at a potential of +80 mV; the basolateral surface faces a perilymph with the composition of normal extracellular fluid, and the cell resting potential is close to -80 mV^{13,14,35,36}. Isolated outer hair cells will tend to lose their internal K⁺ because the large K⁺ reservoir which drives K⁺ across the apical surface in vivo is absent when the isolated cells are placed in normal (5.5 mM) $\rm K^+$ saline. Low levels of internal $\rm K^+$ and a gain of $\rm Na^+$ would account for the low resting potentials of isolated cells, the reversal potential of K⁺-selective channels in the cell-attached mode and their 'flickery' block at positive membrane potentials.

Our demonstration, in isolated cells, of a Cd2+-sensitive conductance at potentials more negative than -100 mV leads us to suppose that outer hair cells have a transduction channel much like that described by Ohmori for chick vestibular hair cells¹². Such channels have a high permeability for Ca²⁺ and are blocked by Ca2+-channel blocking agents. Perhaps damage to the cochlea due to noise (which often involves outer hair cells) arises from a reduced Ca2+ influx through the disrupted transduction pathway. The reduced activity of the Ca2+-activated channels that we have described would account for the previously reported decrease in K⁺ permeability in noise-damaged cells³⁷

At no time during whole-cell recording did we observe an oscillatory ringing of the membrane potential like that found in auditory hair cells of lower vertebrates⁷⁻⁹. The voltage-dependent channels we have observed were activated at voltages outside the normal range for mammalian cells^{13,14}, therefore we conclude that transduction in outer hair cells and lower vertebrate hair cells operates along different principles.

Isolated outer hair cells exhibit motile responses when current is injected into them⁴⁻⁶. This movement may be seen even in Cd²⁺-containing solution and it appears to depend on transmembrane current rather than on the polarity of the axially flowing component. The function of the Ca²⁺-activated K⁺ conductance may be to clamp the cell close to its K⁺ equilibrium potential and maximize the inward driving force for cations across the transduction channel at the apical surface. In this scheme the large outward current generated across the basolateral surface would directly couple the sensory stimulus to the cell's mechanical response.

Lithium-induced respecification of pattern in Xenopus laevis embryos

Kenneth R. Kao, Yoshio Masui & Richard P. Elinson

Department of Zoology, University of Toronto, Toronto, Ontario, Canada M5S 1A1

Much interest in vertebrate embryology is now focused on early pattern formation in the frog, Xenopus laevis. In this species, the body plan is specified by a stable positional system set up by a cytoplasmic rotation in the zygote that occurs before first cleavage1-4. Perturbation of this initial cellular event by a variety of means causes permanent distortions of the positional system4 Until now it has not been possible to alter the positional system after it has been specified. However, we report here that lithium, when applied after specification of the body plan, can respecify the positional system of the Xenopus embryo such that dorsal, axial structures develop from cells that otherwise contribute to ventral structures. Lithium is usually considered to have negative effects on early embryo development⁸⁻¹⁰, but our results show that lithium can act in a positive manner to produce structures which represent the uppermost values of the positional system. This discovery introduces a convenient means to study cellular and molecular mechanisms of early vertebrate pattern expression.

When dejellied 32-cell Xenopus laevis embryos are exposed to Li+ (such as 20% Steinberg's solution with 0.3 M LiCl for 6 min) they develop exaggerated head or dorso-anterior structures. They form multiple eyes or large bands of retinal pigment, and in some batches of eggs, the embryos develop a long proboscis. These embryos resemble morphologically those produced by exposure to deuterium oxide (D2O) before axis specification, and are considered to have enhanced dorsal structures4. Backström9 reported similar results which he considered to be Li*-induced 'ventralization'. However, the parallels between the morphologies produced by Li⁺ and those produced by D2O suggest that Li⁺ is causing enhancement of dorsoanterior development.

To confirm that Li+ causes dorso-anterior development, we applied Li⁺ to cleavage stage embryos which had been irradiated with ultraviolet (UV) light before first cleavage^{6,7}. UV-irradiated embryos lack all dorsal structures including the central nervous system, notochord and somites, and they remain as a radially symmetric ventral mass. However, dorsal structures can be

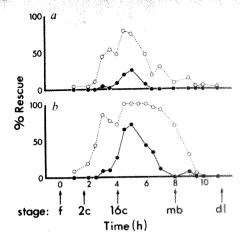

Fig. 1 Rescue of dorso-anterior development by LiCl in radially symmetric, ventral embryos produced by UV-irradiation. The horizontal axis represents the time in hours following fertilization with corresponding stages of development, f, fertilization; 2c, two cells; 16c, sixteen cells; mb, mid-blastula; dl, dorsal lip. The vertical axes represent the percentage of embryos showing axis development in response to 0.2 M Li⁺(a) and 0.3 M Li⁺(b) (35-87 embryos per treatment group). O, Percentage of embryos showing dorsal development, ranging from those showing somites and tail fin (IAD) grade 4) to those showing dorso-anterior radial development as in Fig. 2a and 2b. , Percentage of embryos showing exclusive dorsoanterior development. Note the peak in sensitivity to Li* at 5 to 6 hours of development (32 to 64 cells). As judged from the area under each curve, the higher concentration of Li⁺ was able to effect more rescue than the lower concentration.

Methods. Xenopus laevis eggs were fertilized and dejellied as described previously12. The vegetal poles were irradiated with UV light fort 2 min at a distance of $2\frac{1}{2}$ cm through a quartz slide within 30 min after fertilization. For these experiments, we used a pulse treatment of a high Li+ concentration for short duration in order to resolve the period of Li+ sensitivity. Irradiated embryos were incubated for 5 min at various times after fertilization in solutions of either 0.2 M or 0.3 M LiCl dissolved in 20% Steinberg's solution. Irradiated embryos not treated with LiCl developed into radially symmetric, ventral embryos. A few (usually <1%) develop a small tail fin but with no dorso-anterior development. After the LiCl treatment, embryos were thoroughly washed several times with 20% Steinberg's solution immediately and intermittently for several hours thereafter. All experiments and raising of embryos were done at 20 °C. Embryos were scored for development when untreated controls were at stage 4013

rescued when these ventralized embryos are exposed to Li during early cleavage. Two different patterns of rescue emerge from such treatment: dorso-posterior and dorso-anterior rescue. The dorso-posterior embryo is identical to the grade-4 axisdeficient embryo classified by Scharf and Gerhart's index of axis deficiency (IAD)7. The grade-4 embryo has somites and a tailfin but completely lacks a head. The other type of rescued embryo develops only dorso-anterior structures. Some develop a head with a cement gland and small amount of retinal pigment (Fig. 2a), while others have radial dorso-anterior development with a wide band of retinal pigment and a cement gland encircling the head (Fig. 2b). The frequency of embryos displaying exclusive dorso-anterior rescue and those showing rescue of any dorsal structures depends on dosage of Li* and the time of treatment (Fig. 1). The most sensitive period for rescuing UV-irradiated embryos with Li⁺ is between the 32- and 64-cell stages. Thus, the presence of dorsal structures in embryos otherwise lacking them suggests that Li⁺ is activating, some time during early cleavage, those components that are responsible for dorsal differentiation.

The radial arrangement of dorso-anterior structures produced by Li⁺ treatment suggests that Li⁺ is acting evenly around the embryo. We microinjected Li+ into specific cells of UV-irradi-

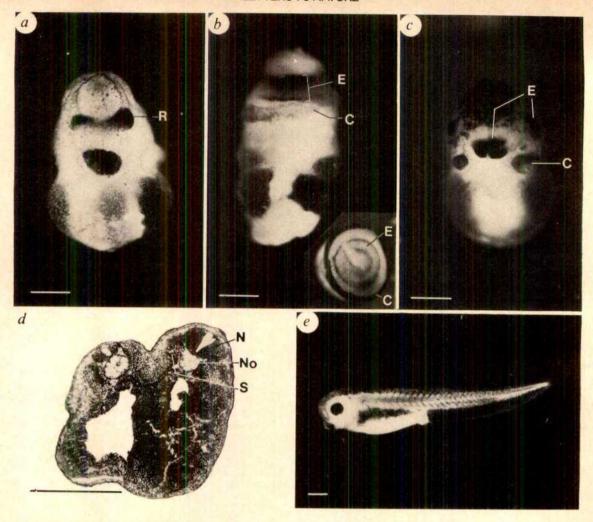

Fig. 2 a, X. laevis embryo exposed to UV light prior to first cleavage and then treated with 0.3 M LiCl for 5 min at the 32-cell stage. Note the presence of retinal pigment (R) which would not develop without LiCl exposure. b, An embryo with dorso-anterior radial symmetry. This embryo, like that in a, was UV-irradiated. Exposure to 0.3 M LiCl for 5 min 4.5 h following fertilization (16-32 cells) restored dorso-anterior development, causing rescue of eye (E) and cement gland (C) in a radial manner (inset: top view of radial, anterior embryo). c, A 'Janus twin' embryo exhibiting duplication of dorso-anterior structures. This embryo was injected with 4 nl of 0.3 M Li⁻¹ into a ventral, vegetal cell at the 32-cell stage. The eyes (E) and cement gland (C) of the head on the right side are labelled. d, A section just posterior to the head of an embryo displaying duplication of the head with one posterior axis. This embryo was microinjected similarly to the embryo in c. Embryos were fixed, sectioned in paraplast and stained as described previously¹². The duplicate axis is unlabelled. No, notochord; N, neural tube; S, somites. See Fig. 4 for experimental details. e, A control, untreated embryo at stage 40. Scale bars, 0.5 mm.

ated embryos to try to restore dorso-anterior development to one side of the embryo and thereby rescue normal development. Embryos at the 32-cell stage were used because they could be easily injected without significant leakage, and were most sensitive to rescue by Li+. Microinjection of Li+ into a cell in the vegetal-most tier caused significant rescue of normal development in a dose-dependent manner (Fig. 3). We used the IAD to quantify axis development, because the embryos developed morphologies identical to those defined by the IAD scale. For example, in Fig. 3, vegetal cell injections of 0.3 M Li+ reduced the average IAD to 2 in embryos which would otherwise develop into grade 4.9 or 5 embryos. Out of 81 embryos, 30% were scored as grade 0 (normal), 13% as grade 1 (slightly microcephalic), 16% as grade 2 (cyclopic), 17% as grade 3 (microcephalic), 16% as grade 4 (acephalic), and 8% as grade 5 (radial ventral). We could not assign an IAD score to embryos injected with solutions of Li⁺ greater than 0.3 M. These concentrations approach lethal levels and in the surviving embryos, there is an over-enhancement of dorso-anterior structures so that the embryos tend towards radial dorso-anteriorization. Injection of Li+ into an animal cell gave a lower frequency of rescue than with vegetal cell injections. It remains to be determined whether

the injected vegetal cell is altered by Li⁺ or whether it acts as a local source of Li⁺.

The restoration of bilateral symmetry in UV-irradiated embryos by Li+ microinjection prompted us to determine whether dorsal structures are duplicated in normal embryos when they are microinjected with Li+. We microinjected into vegetal lower-tier cells as this injection gave the best rescue of UV-irradiated embryos. From 112 embryos microinjected with Li⁺ into a ventral, vegetal cell, we obtained 97 embryos that had duplication of dorso-anterior structures (Fig. 4). Most of these embryos developed into 'Janus' twins (Fig. 2c) that lack posterior development but consist of two heads which have normally formed eyes and cement glands. A small number (~5%) developed into twins which have a single posterior axis but with twinned heads, central nervous systems, notochords and somites (Fig. 2d). Injection into a dorsal cell failed to duplicate dorsal structures. Out of 97 embryos injected into a dorsal, vegetal cell, 89 survived to form a single body axis. Most (~80%) developed normally, but the remainder developed enhanced dorso-anterior structures, similar in external appearance to the 'imbalanced' embryos produced by Cooke5

To see whether dorsal rescue is specific for Li+, we microinjec-

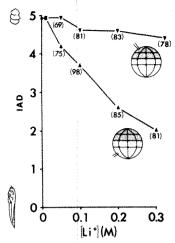

Fig. 3 Rescue of normal development by Li⁺ microinjection into radially symmetric ventral, embryos, Embryos were fertilized and irradiated with UV light as described in Fig. 1, and then microinjected with 3-5 nl of LiCl dissolved in distilled H2O or 200% Steinberg's solution at varying concentrations (horizontal axis) into either a top mostanimal tier cell (♥) or lowest vegetal tier cell (▲). The embryos for each experimental group were scored for axis development (vertical axis) using the index of axis deficiency (IAD)[†]. An IAD score of 0 indicates normal development whereas a score of 5 indicates complete lack of dorsal structures with only radial ventral development. The average IAD is plotted here for each group of injected embryos. Note that the average IAD is reduced in both animal and vegetal cell injections, but more significantly in the latter. Microinjection of >0.3 M Li⁺ increased the frequency of dead embryos and the formation of exclusively dorsoanterior embryos that are not scorable with the IAD. The numbers in brackets refer to numbers of embryos injected with LiCl at the indicated concentration. (For 0.01 M LiCl, 78 embryos were microinjected in the animal cell and 86 embryos were injected into the vegetal cell. At 0 M, 269 control embryos were scored.)

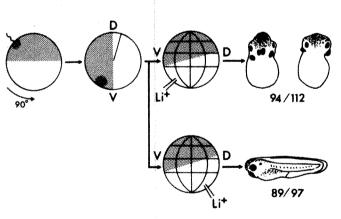

Fig. 4 Summary of twinning experiments. Fertilized eggs were placed in a 5% solution of Ficoll (Pharmacia) in 20% Steinberg's solution and rotated within 30 min after fertilization with the sperm entry point (SEP) towards gravity. The rotation ensures the position of the dorsal side of the embryo (D) as 180° opposite the SEP (ventral side, V) in the meridian passing through the SEP and the animal-vegetal axis. Eggs were kept in this orientation for 20 to 30 min and the dorsal (upper) side was marked with Nile blue sulphate14. After the rotation period, eggs were allowed to orient normally in 20% Steinberg's solution with the vegetal pole downwards. At the 32-cell stage, embryos were microinjected either in a ventral, vegetal-most cell or a dorsal, vegetal-most cell with 3-5 nl of 0.3 M LiCl dissolved in 200% Steinberg's solution. At stage 40, the embryos were scored for development either as having a single body axis or with duplicated dorso-anterior development. The twins resulting from ventral cell injection are usually Janus twins with two diametrically opposed anterior ends, although some show closely approximated heads as in Fig. 2c.

ted 4 nl of 0.4 M solutions of NaCl, KCl, CsCl, RbCl or NH₄Cl, 50 mM solutions of CaCl2 or MgCl2, or a 10 mM solution of ZnCl₃ (higher concentrations of the latter three salts usually killed the embryos). All solutions were made up in 200% Steinberg's solution which, when injected alone into UV-irradiated embryos, did not cause rescue. Among the cations tested, only Li⁺ was able to cause significant rescue of dorsal structures.

Based on cell transplant experiments Gimlich and Gerhart¹¹ showed that a vegetal, dorsal cell at the 32-cell stage carried sufficient information to promote complete dorsal development. This information is translated by inductive cell interactions during cleavage to form dorsal elements. Our experiments show that Li⁺ is able to cause expression of dorsalizing information in cells that otherwise lack or do not express this information. Thus, the potential for cells to undergo dorsal development exists radially around the embryo even after axis specification. and such development will occur when stimulated by Li* at the appropriate time.

The ability to produce radial dorsal embryos with L should facilitate investigations on the molecular and cellular differences between dorsal and ventral pattern formation in X. laevis.

We thank JoAnn Render for initial discussions. This work was supported by a grant to R.P.E. from NSERC, Canada.

Rabies, a viral disease affecting all warm-blooded animals, is prevalent in most parts of the world1, where it propagates amongst wild animals, particularly the fox and dog. The public health and economic consequences of infection in man and livestock are well known. Attempts to control the disease by vaccinating wild carnivores with inactivated or attenuated rabies virus remain controversial, and we have instead evaluated here the potential of a recombinant vaccinia virus to protect foxes against the disease. We have found that the administration of vaccinia virus (VV) or a recombinant harbouring the rabies surface antigen gene (VVTGgRAB) is innocuous to foxes. The recombinant virus can elicit the production of titres of rabies-neutralizing antibodies equal or superior to those obtained with conventional vaccine, and 108 plaque-forming units (PFU) of VVTGgRAB administered subcutaneously, intradermally or orally confers complete protection to severe challenge infection with street rabies virus.

Rabies neutralizing antibody titres were determined in accordance with recommendations laid down by the World Health Organisation²⁷. Titres are expressed as the log₁₀ of the final neutralizing dilution (FND). For conversion to international units (IU) IU = 59/[antilog (3.5 - log FND)]. Foxes were monitored for 50 days following challenge and the presence of rabies virus in the brain of the animals succumbing to challenge was verified by immunoflorescence (not shown). Challenge virus GS6 (street virus comprising salivary glands from rabid foxes dispersed in phosphate-buffered saline (PBS) (20% w/v) as described previously²⁸) was injected in a volume of 1 ml containing 5,700 mouse LD₅₀ units (intracerebral), ~17,000 fox LD₅₀ units (intramuscular). Vaccinia Copenhagen strain and VVgRAB were grown on tissue culture cells as described elsewhere²⁹. Supernatants were recovered, the cell pellets homogenized, recentrifuged and pooled with the supernatant. Virus was purified by sedimentation through a sucrose cushion (36% w/v) for 2 h, 14,000 r.p.m., Beckman SW28 rotor. Pellets were suspended into PBS, sonicated briefly and banded by centrifugation on a sucrose gradient (20-40% w/v; 12,000 r.p.m., 45 min, SW28) before diluting (PBS) to the required concentration. Virus was titred on BHK21 cells. NA, not applicable.

* Only the 28-day titre is given.

- †+, Resisted challenge, -, succumbed to rabies. All animals not resisting died between 15 and 25 days after challenge.
- ‡ 'Rabisin ND' vaccine, lot 5532; neutralizing antibody titres obtained with live attenuated virus are similar (not shown).
- § Virus was inoculated intradermally as described (see text); subcutaneous injections were performed in a volume of 1 ml.
- Virus was administered by direct application into the mouth by syringe (vol. 1 ml).
- ¶ Two animals were observed to have ingested only a part of the vaccine.
- # Four animals were vaccinated with vaccinia virus Copenhagen strain, two animals received no treatment.

Transmission of rabies occurs predominantly through biting. Large quantities of virus are shed in the saliva and the aggressive behaviour of the rabid animal facilitates transmission. Infection by this route is invariably fatal and an immune population is therefore never established. Prophylactic measures have aimed at eliminating or reducing the population of the principal reservoir through poisoning or gassing², though a decrease in the carrier population density rarely reduces the rate of advance of the disease front³. In Europe, culling of foxes has reduced the number of rabies outbreaks but has not contained the disease. Vaccination, perhaps supported by culling in low-density fox populations, seems more likely to be effective than mere destruction of foxes⁴. An immune population is better able to limit the spread of the disease than one which is sparse but susceptible^{4,5}.

Oral administration could facilitate the vaccination of large numbers of wild foxes and this was first attempted in North America and Europe^{6,7}. Live attenuated rabies virus introduced into chicken heads, sausages or dog biscuits and distributed in the wild has been successfully used to vaccinate wild foxes⁸, and field trials are in progress in Switzerland, West Germany⁹ and Canada (C. D. MacInnes, personal communication).

However, the virus is often unstable and attenuated viruses retain pathogenicity for rodents and can revert to virulence¹⁰. Furthermore, inactivated rabies virus is ineffective when administered orally¹¹. A novel vaccination strategy, in which a recombinant vaccinia virus bearing a foreign antigen coding sequence is used as the immunizing agent¹²⁻¹⁴, seemed to hold some promise for the vaccination of foxes against rabies.

The causative agent of rabies is a rhabdovirus, and the glycoprotein (G) which traverses the envelope surrounding the virus, is the sole viral protein capable of inducing and reacting with virus-neutralizing antibodies or of conferring protection against rabies^{15,16}. The relative innocuity of vaccinia virus, which has been used extensively to control and eradicate smallpox in man¹⁷, has stimulated its development as a cloning and expression vector, and derivatives expressing surface antigens from influenza, hepatitis B and herpes simplex have been used to confer protection against these diseases¹⁴. We recently developed a recombinant VV (VVTGgRAB) expressing the rabies G coding sequence¹⁸ and found that mice scarified with the live recombinant virus VVTGgRAB resisted severe challenge with street rabies virus¹⁸⁻²⁰. VV itself is an enveloped virus and

the recombinant VVTGgRAB presenting rabies G protein elicited protection against rabies even after chemical inactivation¹⁹. We therefore extended our investigations to wild foxes.

Vaccinia virus (Copenhagen strain) was first tested for innocuity to foxes. European foxes (Vulpes vulpes) of both sexes captured in the wild and raised in captivity as described previously²¹ were inoculated with live vaccinia virus. Two animals (nos 445, 448) received VV by injection (vol. 0.1 ml) into the depilated skin of the back and two further animals (446, 449) received the recombinant VVTGgRAB by the same route. 102, 104, 106 or 108 PFU of virus were injected at triplicate sites and cutaneous reactions monitored for 15 days.

Mild localized inflammation was observed at the sites of injection with 106 or 108 PFU of virus, and in one animal (445) at 102 and 104 PFU. In all cases inflammation regressed spontaneously within 8 days. Cutaneous reaction was significantly greater with the wild-type strain of VV than with the recombinant VVTGgRAB strain (not shown). No lesions appeared elsewhere than at the site of injection and there was no evidence here of contact transmission of vaccinia virus between animals. In test animals receiving live recombinant vaccinia virus by direct application into the mouth (Table 1) no impairment of digestive or alimentary function was observed.

We subsequently examined the ability of the recombinant virus to elicit the production of antibodies directed against rabies virus. Animals inoculated intradermally, subcutaneously or orally with VVTGgRAB were bled on days 0, 8, 14 and 28; serum was separated and titred for the presence of rabiesneutralizing antibodies. High titres of neutralizing antibodies were present in sera from all but one animal treated with 108 PFU of VVTGgRAB (Table 1). Further, scarification of oral mucous membranes before oral administration (to facilitate penetration of the virus) did not yield improved titres of neutralizing antibodies. All animals presented only low levels of antibody capable of neutralizing VV (not shown), in agreement with other reports²².

Direct protection testing was then performed. Twenty-eight days after vaccination, animals were challenged by injection of 5,700 mouse LD₅₀ (50% lethal dose) units of rabies virus. All 12 animals recieving 108 PFU of VVTGgRAB either orally or parenterally resisted challenge (Table 1). One animal (442) exhibiting undetectable levels of rabies-neutralizing antibodies also resisted challenge, attesting to the relevance of cell-mediated immunity in defence against rabies 16,23. Control animals receiving no vaccine succumbed to the disease after 15-25 days. Two animals injected subcutaneously with a commercial inactivated (adjuvanted) vaccine similarly resisted challenge, although virus-neutralizing antibodies were present at a reduced level (Table 1). Oral administration of conventional (inactivated) vaccine has previously been shown to be ineffective11.

Animals receiving less than 108 PFU of VVTGgRAB showed a clear dose-dependent response, with one out of four and two out of four animals surviving challenge after oral administration of 10⁴ and 10⁶ PFU of VVTGgRAB, respectively (Table 1).

Oral administration is the only route appropriate to the vaccination of wild animals. Accordingly, the vaccine must be presented in a form suitable for ingestion. We thus prepared 'Plastipak capsules (a gift from Dr Wandeler) containing 108 PFU of VVTGgRAB, inserted them into chicken heads (one capsule per head into the beak) and distributed them to test animals (one per fox). These animals similarly produced high titres of rabies-neutralizing antibodies and resisted severe challenge with rabies virus (Table 1).

Transmissibility is a major factor determining the impact of a live vaccine on a wild population. We therefore sought to establish whether animals vaccinated with VVTGgRAB might transmit the virus by contact with untreated control animals. Four test animals (two male, two female) were acclimatized (4 days) to sharing a pen (2 m²) with an animal of the opposite sex. One animal from each pair received 108 PFU of live

VVTGgRAB by direct application into the mouth (vol. 1 ml). Serum samples were collected from both vaccinated and control animals at 14 and 28 days, and intramuscular challenge with live rabies virus (see Table 1 legend) was performed at 28 days.

All vaccinated animals presented high titres of rabiesneutralizing antibodies (mean 2.72 at 28 days, units as in Table 1) and resisted challenge. In three out of four control animals no rabies-neutralizing antibodies were detectable and these animals succumbed to challenge (not shown). Surprisingly, the fourth control animal (523, female) presented significant levels of rabies-neutralizing antibodies (1.35 and 0.97 at 14 and 28 days, respectively) and resisted severe challenge infection.

Subsequent investigations into possible mechanisms of transmission revealed that both the relevant vaccinated male (517) and control female 523 consistently displayed aggressive behaviour, and reciprocal biting was observed within a few minutes of oral vaccination. Contamination of bite wounds with VVTGgRAB may, in this instance, have been sufficient to effect immunization. Such a mode of transmission requires a combination of rather exceptional circumstances, and we surmise that contact transmisson of VVTGgRAB in the field is likely to be

We have shown that vaccinia virus and its recombinant VVTGgRAB bearing the rabies surface antigen are innocuous to healthy foxes; indeed, the thymidine kinase-negative recombinant may be more innocuous than wild-type strains of vaccinia virus²⁴. Our recombinant virus can confer complete protection to severe challenge infection with rabies virus. Similar experiments are in progress with other animal vectors of rabies, notably the skunk and racoon25. Importantly, presentation to foxes of the live recombinant, encapsulated and introduced into chicken heads, also yields animals resisting severe challenge infection. Procedures for the production, stabilization and distribution of vaccinia virus are fully established26. Due to its efficacy, innocuity and stability, the recombinant virus may be a candidate for the large-scale vaccination of wild foxes and, possibly, other feral or domestic animals.

We thank H. Koprowski and T. Wiktor for helpful discussion and for communicating unpublished data, R. Thomas for his practical suggestions concerning this study, D. Schmitt, K. Dott, J. Bailly, M. Sleve and E. Cain for technical assistance and N. Monfrini and L. Schneider for help in preparing the manuscript. We dedicate this manuscript to the late Dr T. Wiktor.

Preferential expression of a defined T-cell receptor β-chain gene in hapten-specific cytotoxic T-cell clones

Ute Hochgeschwender*†, Hans Ulrich Weltzien†, Klaus Eichmann†, R. Bruce Wallace* & Jörg T. Epplen*

* Junior Research Unit and † Department of Cellular Immunology, Max-Planck-Institut für Immunbiologie, D-7800 Freiburg, FRG

A multitude of different antigens can be recognized by T cells through specific receptors. Both the α - and β -chains of the T-cell receptor contribute to the antigen recognition portion1. The repertoire of β -chain variable region (V_{β}) gene segments is limited to some 20 elements²⁻⁴ which seem to be used randomly in different T cells^{2,5,6}. Diversity at the β-chain level can be created in several ways^{2,3,7-12}; a multiplicity of germline gene segments; combinatorial diversity by rearranging different V, diversity (D), joining (J) and constant (C) region elements; junctional diversity by joining gene segments at different sites; N-region diversity, that is, insertion of random nucleotides at junctional sites; and somatic mutation¹³. However, the major sources and the extent of diversity of the T-cell receptor are unclear. To address this issue, 42 H-2Kb-restricted, 2,4,6-trinitrophenyl (TNP)-specific cytotoxic T-cell (Tc) clones from C57BL/6 mice were characterized with respect to expression of different β-chain gene segments in messenger RNA using specific oligonucleotide probes. We report here that nearly half of the T_c clones use identical elements for productive β-chain gene rearrangement. Thus, there is a restriction in the use of β-chain gene segments in this panel of T_c clones which favours a particular $V_{eta}\!-\!D_{eta}\!-\!J_{eta}\!-\!C_{eta}$ combination with a defined D_{α} element.

A collection of 42 class I (H-2K^b) restricted cytotoxic T-cell clones possessing specificity for the hapten TNP has been established ¹⁴. In order to isolate and characterize the expressed T-cell receptor β -chain gene of a randomly chosen T-cell clone, a complementary DNA library was constructed in the bacteriophage vector λ gt11 from total cellular RNA of T_c clone 112-2. The nucleotide sequence of a β -chain cDNA clone (pBJ2.1) was determined as $V_{\beta}3$ - $D_{\beta}112$ -2- $J_{\beta}2$ -6- $C_{\beta}2$ (nomenclature according to ref. 2; $V_{\beta}3$ is termed $V_{\beta}2B4$ in ref. 7 and $V_{\beta}13$ in ref. 3), whereby $D_{\beta}112$ -2 is a segment of seven nucleotides partly different from the known germline sequences of $D_{\beta}1$ -1 or $D_{\beta}2$ -1 (Fig. 1a).

Synthetic oligonucleotides were prepared which were specific for the V, D and J segments of T_c clone 112-2 (Fig. 1a) in order to determine the frequencies with which the $V_{\beta}3$, $D_{\beta}112-2$ and J_{β} 2-6 gene segments are used in the panel of T_{c} clones. Furthermore, oligonucleotides specific for the $C_{\beta}1$, $C_{\beta}2$ and C_{α} gene elements were used for sequential Northern blot or direct gel hybridizations. An example is shown in Fig. 1b in which hybridizations of an RNA gel with the set of oligonucleotide probes reveal the individual elements expressed in β-chain mRNAs of the different T_c clones. We found that 19 out of 42 (45%) T_c clones use the same V_{β} 3 gene segment as T_c clone 112-2 (see Fig. 2). Moreover, whenever the V_B 3 gene segment is expressed, it is always rearranged to D_{β} 112-2, J_{β} 2-6 and C_{β} 2 as in T_c clone 112-2 (see Figs 1b, 2). Therefore, 45% of the H-2Kb/TNP-specific T_c clones must use identically composed β-chain genes for the T-cell receptors. In half of the remaining T_c clones, different V_{β} and D_{β} elements are joined to the $J_{\beta}2-6-C_{\beta}2$ gene segments, while 30% of all T_c clones use additional V_{β} , D_{β} and J_{β} elements in connection with either $C_{\beta}1$ or $C_{\beta}2$.

To obtain additional evidence that the D elements used in individual T_c clones are identical—in particular with regard to the V-D and D-J junctions—probes were designed with one

or two base mismatches at the borders of the $D_{\beta}112\text{-}2$ element (see Fig. 3). EcoRI-digested DNA of cDNA clone pBJ2.1 was probed with the perfectly matched $D_{\beta}112\text{-}2$, the D_{I} (one mismatch at the D-J junction), the D_{II} (two mismatches at the D-J junction) and the D_{III} (one mismatch at the V-D junction) probes under various conditions (Fig. 3). Only the perfectly matched $D_{\beta}112\text{-}2$ probe was able to form stable hybrids under the standard conditions employed. Corresponding results were observed in RNA hybridization experiments (data not shown). Therefore, the finding that 45% of T_{c} clones give positive signals with the $D_{\beta}112\text{-}2$ probe indicates that very similar or identical D elements are being expressed.

The $V_{\beta}3$, $D_{\beta}112-2$ and $J_{\beta}2-6$ oligonucleotide probes were also employed in the DNA hybridization analysis of the panel of H-2K^b/TNP-specific T_c clones using different restriction enzymes. As an example, Fig. 4 shows the gel hybridization pattern obtained with EcoRI-digested DNA from three Tc clones and B6 liver (Fig. 4). Using the $V_{\beta}3$ probe, two germline gene segments were detected in B6 liver DNA, while the band of high relative molecular mass (M_r) corresponds to the $V_{\beta}3$ band of the B10.A mouse (refs 2, 12 and our unpublished results). Sequence analysis of the coding region of the B6 germline $V_{\rm g}3$ element revealed identity with the known segment from B10.A mice. Southern blot and DNA gel hybridizations of all V_B 3positive T_c clones revealed identical productive V_B3 rearrangements (data not shown), suggesting that only the element of the high- M_r band is used. With the $V_B 3$ and $J_B 2$ -6 probes, in addition to germline elements, rearranged gene segments were detected in T_c clones. Hybridization of the D_{β} 112-2 oligonucleotide to the DNAs produced a signal exclusively in a T_c clone in the same position as the productively rearranged $V_{\beta}3$ and $J_{\beta}2$ -6 elements (Fig. 4). The hybridization specificity and design of the D_{β} 112-2 probe (Fig. 1a) ensures that a positive signal can be obtained only when D_{β} 112-2 is rearranged to the V_{β} 3 and J_{β} 2-6 gene segments. All the T_c clones that scored positive for the complete preferentially expressed V_{β} gene showed the single D_{β} 112-2 band of Fig. 4 (data not shown). In additional Southern blot hybridization, the rearrangements of the $C_{\beta}1$ and $C_{\beta}2$ loci were investigated in T_c clones which did not hybridize with V_a 3. D_{β} 112-2 or J_{β} 2-6 probes. Nick-translated and oligonucleotide probes specific for the $J_{\beta}1$ and $J_{\beta}2$ clusters revealed heterogeneous rearrangements in $J_{\beta}1$ for the $C_{\beta}1$ -positive T_{c} clones and in $J_{\beta}2$ for the $C_{\beta}2$ -positive T_{c} clones (data not shown). With regard to the productive rearrangements, this heterogeneity stands in contrast to the uniformity observed in the group of T_c clones that express the defined V_{β} gene.

Although there have been no similar studies of T-cell receptor β-chain diversity in an antigen-specific restricted immune response, data are available on Southern hybridization experiments of cytochrome c-specific T-helper (Th) hybridomas15 and bulk T-cell lines specific for hen egg white lysozyme5. Both reports present evidence that similar or identical β-chain gene rearrangements have occurred in the DNA of their isolated Th cells from the same immune response. It is assumed, therefore, that these T_h cells express identical V_{β} genes. Our investigation shows clearly that in a collection of T_c clones specific for the same antigen (H-2Kb/TNP), a defined complete T-cell receptor β-chain gene is preferentially expressed. The reasons for this are unknown, but the situation is reminiscent of observations of humoral immune responses; in the mouse the antibody response to certain model antigens¹⁶⁻¹⁹ is characterized by the dominant expression of one or a few related immunoglobulin heavy-chain V-region genes by antibody-secreting lymphocytes. In contrast to the similarities to V-gene expression in B- and T-cell receptors in defined immune responses, the choice of the D segment appears to be restricted only in the β -chain of T_o clones. D-region identity is not found in specific humoral immune response. In immunoglobulins, the V regions of heavy chains are often almost identical, whereas the D segments are extremely variable 16-18, although antigen recognition is

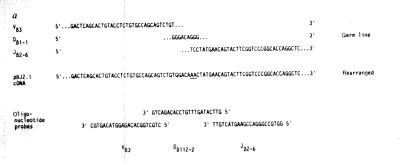

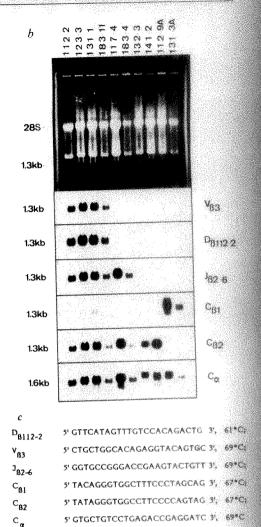

Fig. 1 a, Sequences of the V_{β} , D_{β} and J_{β} gene segments in germline configuration and after rearrangement in the TNP-specific T_c clone 112-2, illustrating junctional and N-region diversity. cDNA clone pBJ2.1 is compared with published germline gene segments $V_{\beta}3$ (ref. 7), $D_{\beta}1$ -1 (ref. 11) and $J_{\beta}2$ -6 (ref. 7). At least two nucleotides (underlined) at the D-J joining of pBJ2.1 are encoded by neither the germline D_{β} nor the J_{β} segment. The oligonucleotide probes $V_{\beta}3$, $D_{\beta}112$ -2 and $J_{\beta}2$ -6 are complementary to the mRNA and depicted below the cDNA sequence. b, Gel hybridization analysis of RNA from 10 different T_c clones specific for H-2Kb/TNP using six different $J_{\beta}2$ -P-labelled oligonucleotide probes specific for different T-cell receptor gene segments. kb, kilobases.

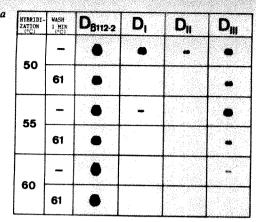

Methods. a, A cDNA library was constructed from total cellular RNA of Tc clone 112-2 in the bacteriophage vector Agt11. Screening was carried out according to ref. 22, using a nick-translated probe (AK1)²³ which hybridizes with the constant region of the T-cell receptor β-chain gene. Positive clones were isolated and plaque purified. A hybridizing cDNA clone from the 112-2 library was subcloned into pUC12 (pBJ2.1) and into M13mp9. Sequence analysis of pBJ2.1 was carried out according to Sanger et al.24. The sequence of the 740-base-pair (bp) insert of pBJ2.1 consists of the 3' end of a V_{β} (~100 bp), a D_{β} and a J_{β} element as well as a complete C_{β} (including some 50 bp of 3' untranslated sequence). b, RNA from cultured cells was extracted in the presence of guanidinium thiocyanate²⁵ and pelleted by centrifugation through a 5.7 M caesium chloride cushion. RNA (10 µg) was denatured in the presence of formaldehyde and agarose gel electrophoresis was performed26. The ethidium bromide-stained gel was photographed under ultraviolet light (top) and dried27 or blotted onto GeneScreen (NEN). Oligonucleotides were synthesized on an automated DNA synthesizer and radiolabelled using $[\gamma^{-32}P]ATP$ and T4 polynucleotide kinase²⁸. All hybridizations and washing steps were carried out according to ref. 18. c, The same gel has been hybridized consecutively with various probes (in the order given) at 60 °C and was washed for 1 min at the indicated temperatures. The washed gel was exposed to Kodak XAR-5 films using Quanta III (Dupont-Cronex) intensifying screens for approximately 40 h. After each exposure, probes were removed by washing the gel in 5 mM EDTA at 60 °C. Washing efficiency was monitored by control exposures.

Fig. 2 T-cell receptor β-chain genes of H-2Kb/TNP-specific To clones. The 42 T_c clones are listed according to their β-chain gene structure as determined by Northern blot or RNA gel hybridizations with specific oligonucleotide probes (see Fig. 1b legend for a description of the probes). The panel of T_c clones was derived from seven individual mice. Briefly, 5-6-week-old female C57BL/6 mice were immunized with TNP^{29,30}. Cultures from spicens of immunized mice were established 10 days later with immune spleen cells and irradiated B6 spleen cells coupled with TNP as stimulator cells in medium containing interleukin-2. From 32 independent cell lines, 42 T_c clones were derived from cultures containing on average 0.5 cells per culture. According to Poisson statistics, at least 77% of the 42 clones should have been derived from a single cell while up to 10 may have been derived from 2 or more cells 4 T_c clones were grown in the presence of stimulator cells and interleukin-2 by weekly restimulation. Cells were collected for extraction of RNA and DNA 4 days after restimulation. At the time of RNA and DNA extraction, Tc clones investigated have been in continuous culture for 5-8 months. In some cases the cells had been frozen, then thawed and regrown for RNA and DNA extraction (indicated by 'A'). T_c clones were tested for cytotoxic function and H-2Kb/TNP specificity at monthly intervals in a 51Cr-release assay. Clones were numbered according to the series of immunization, the individual mouse, the individual cell line derived from the spleen of a certain mouse and the cultures obtained after cloning: for example, T_c clone 112-2 is from series 1, mouse 1, line 2, clone 2.

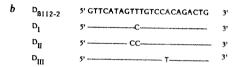

Fig. 3 a, Hybridization specificity of the oligonucleotide probe $D_{\rm B}$ 112-2 and three derivatives with base mismatches at the V-Dand D-J junctions. pBJ2.1 (3 μg) was digested with EcoRI, divided into six identical aliquots and subsequently subjected to electrophoresis in a 0.75% agarose gel³¹. After denaturation, neutralization and drying of the gel²⁷, the six individual lanes were cut. b, Gels strips were consecutively hybridized with the D_B 112-2 probe and its derivatives. After hybridization at the indicated temperatures, each gel strip was washed in 6×SSC at room temperature. Half of the gel strips were then washed for 1 min at 61 °C as indicated. Steps were exposed for 15 h without intensifying screen. After each hybridization the probe was removed and gel strips re-exposed to exclude any remaining signal.

maintained. This indicates that the D regions of heavy chains are involved in idiotypy^{20,21}. There is no obviously analogous role for the D region in the T-cell receptor β-chain.

The finding that 45% of the H-2Kb/TNP-specific T_c clones express very similar or identical D_{β} elements is unexpected in view of the fact that the $D_{\beta}112-2$ element is not identical to known germline D_{β} elements. If the germline D_{β} 1-1 element is assumed to be used, at least two bases (AA) at the borders of the D_{β} - J_{β} junction are not germline encoded (see Fig. 1a) and consequently are generated by a random process². If one assumes that the β -chain D region is important for antigen

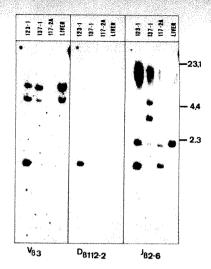

Fig. 4 Analysis of DNA from T_c clones specific for H-2K^b/TNP and from liver of the B6 mouse.

Methods. Cellular DNA was extracted modified according to ref. 31. DNA (10 µg) prepared from T_c clones was digested to completion with the restriction enzyme *EcoRI*. DNAs were electrophoresed in 0.75% agarose gels³¹. After denaturation and neutralization the gel was dried²⁷ and hybridized consecutively with the oligonucleotide probes J_{β} 2-6, D_{β} 112-2 and V_{β} 3. (See Fig. 1b legend for a description of the probes.) The gel was exposed for 4 days with intensifying screens. M_r markers are indicated in

binding and that the dinucleotide AA of the AAC codon for asparagine is critical for TNP recognition, then its presence in nearly half of the T_c clones would be due to selection by the antigen. On the other hand, the D_{β} 112-2 element might be encoded by a hitherto undescribed D_{β} segment in which the preferential combination of this D element with $V_B 3$ and $J_B 2-6$ could also be explained by selective forces. We have found evidence (from additional oligonucleotides covering the V_{β} 3- D_{B} 112-2 junction) for independence of the V_{B} 3 and D_{B} 112-2 elements; it remains to be seen how the D_{β} 112-2 element is in fact generated.

Alternative splicing of murine T-cell receptor β -chain transcripts

Mark A. Behlke & Dennis Y. Loh

Howard Hughes Medical Institute, Departments of Medicine, Microbiology, and Immunology, Washington University School of Medicine, St Louis, Missouri, 63110, USA

Variable processing of heteronuclear RNA into multiple, defined species of messenger RNA is a well-established phenomenon in a number of systems, including myelin basic protein1,2, calcitonin3, troponin T4 and immunoglobulins5-7. Within a single B cell, immunoglobulin heavy-chain peptides often exist as two related but distinct species, a membrane-bound form and a secreted form, both of which originate from the same germline constant(C)-region gene via alternative RNA processing pathways5. Furthermore, at certain stages of B-cell development, a single variable(V)-region element can be concurrently expressed in immunoglobulins of both the IgM and IgD isotypes, presumably resulting from the alternative splicing of one variable-region exon to different constantregion genes^{6,7}. We report here the existence of an alternative RNA splicing pathway available to murine T-cell receptor (TCR) β -chain transcripts. Sequence analysis of β -chain complementary DNA clones reveals a C_0 1 species containing a 72-base pair (bp) insertion between the joining (J_{eta}) and C_{eta} elements. This sequence is inserted via an alternative splicing pathway available to $C_{\beta}1$ transcripts. The optional exon is located between the $J_{\beta}1$ cluster and the first exon of C_{β} 1. Interestingly, this element can be spliced to $C_B 2$ in the New Zealand White mouse, in which the $C_B 1$ gene is deleted^{8,9}. Use of the alternative splicing pathway varies between 1% and 18% of total C_{β} clones, depending on the source of isolation.

We previously reported the nucleotide sequences of a series of murine TCR β -chain variable-region genes identified from 15 V_{β} - C_{β} -containing cDNA clones 10. All 15 of these clones contain a somatically rearranged V_{β} - D_{β} - J_{β} element and a C_{β} element, of which 13 clones have the V_{β} - D_{β} - J_{β} element spliced in the expected manner to the C_{β} element. The remaining two clones were both found to contain an identical 72-bp insertion between their J_{β} and C_{β} elements. The insertion of this 72-bp sequence maintains the open translational reading frame seen in conventionally spliced J_{β} - C_{β} -containing cDNAs and results in the addition of 24 extra codons precisely at the J_{β} - C_{β} splice junction 11.12. As such, the 72-bp insertion appears to define the existence of a new exon which is available for alternative splicing of β -chain transcripts. We call this new exon C_{β} 0.

Of the two clones initially found to include this novel sequence, clone B/C-61 contains $V_{\beta}10-D_{\beta}1.1-J_{\beta}1.6-C_{\beta}0-C_{\beta}1$ and clone B/C-77 contains $V_{\beta}8.2-D_{\beta}1.1-J_{\beta}1.6-C_{\beta}0-C_{\beta}1$. (V_{β} nomenclature follows that of Barth *et al.*¹³, as described in Behlke et al.14). Subsequently, a third cDNA clone (B/C-04) which also contained the C_80 exon was obtained. This clone contains $J_{\beta} 1.3 - C_{\beta} 0 - C_{\beta} 1$ and is truncated within the J_{β} element. The nucleotide sequences of these three cDNA clones are presented in Fig. 1a. These clones all originated from a BALB/c thymus cDNA library; two out of four V_{β} -containing clones examined from this library10 contained the alternatively spliced C_{β} 0 exon. To determine whether alternatively spliced C_{β} 0- C_{β} containing clones could be detected in lymphoid tissue other than thymus, the two oligonucleotide probes described in Fig. 1c were used to screen an unamplified B6 spleen cDNA library. Four C_{β} 0-containing clones were identified from a total of 301 that were C_{β} positive. Three of these four clones contain V_{β} elements; their DNA sequences are presented in Fig. 1b. Clone B6-26s contains $V_{\beta}12-D_{\beta}1.1-J_{\beta}1.1-C_{\beta}1$, clone B6-34 contains $V_{\beta}6-D_{\beta}1.1-J_{\beta}1.1-C_{\beta}1$, and clone B6-73 contains $V_{\beta}1-D_{\beta}1.1-$

Table 1 Relative expression of the C_80 exon in cDNA libraries

cDNA library	$C_{\beta}0$	$C_{oldsymbol{eta}}$	Frequency of $C_{\beta}0$	Frequency of $C_{\beta}1$	Total no. of clones screened
C57BL/6 spleen	4	301	1.3%	27%	350,000
C57BL/6 thymus	14	267	5%	32%	60,000
NZW thymus	26	146	18%	*	40,000

cDNA libraries were constructed and screened as described in the legends to Figs 1 and 3. Libraries were also screened with nick-translated probes specific for $C_{\beta}1$ and $C_{\beta}2$; these probes contain only 3' untranslated (UT) sequence and were subcloned from C_{β} 1- and C_{β} 2-containing cDNA clones. It is not clear whether the frequency of C_{β} 0-containing clones in unamplified cDNA libraries reflects the actual frequency of these species in vivo. While we have no way of directly addressing this question for C_8 0-containing transcripts, we can make such a comparison for a different subset of β -chain transcripts. The C57BL/6 spleen cDNA library has been screened for V_{β} usage (complete data to be presented elsewhere); out of 154 C_{β} -positive clones examined, 102 hybridize to probes specific for the 16 known murine V_{β} subfamilies 14, including 19 clones which hybridize to $V_{\beta}8.2$. Thus, 19% (19/102) of known V_{β} -containing clones and 12% (19/154) of total C_{β} -containing clones contain V_{β} 8-subfamily genes in our B6 spleen cDNA library. The anti-TCR monoclonal antibodies F23.1 and KJ16-133 recognize 19% and 13%, respectively, of peripheral T cells in B6 mice^{30,31}. These reagents are believed to identify a subset of β -chain peptides expressing elements of the three-member $V_{\beta}8$ subfamily ^{14,32}. Thus, expression of at least one subset of β -chain clones in our cDNA library approximates the known level of expression of this same subset in vivo. We presume the same will be true for C_{β} 0-containing clones.

* Does not apply.

 $J_{\beta}1.4-C_{\beta}1$. Clone B6-27 (not shown) contains $C_{\beta}0$ spliced as expected to $C_{\beta}1$, but does not contain an identifiable J_{β} or V_{β} element 5' to $C_{\beta}0$. The seven $C_{\beta}0$ -containing clones described above use five different V_{β} elements and four different J_{β} elements, thus the alternative splicing pathway does not prefer any particular J_{β} or V_{β} sequence.

All seven C_{β} 0-containing clones obtained thus far also contain C_{β} 1, implying that the C_{β} 0 exon should be located between the $J_{\beta}1$ cluster and $C_{\beta}1$ in the genome. A BALB/c genomic library was screened with a C_{β} probe, and a phage was isolated which contained both the $J_{\beta}1$ cluster and $C_{\beta}1$. As expected, C_{B} 0-specific probes hybridize to this genomic clone. A restriction map of the $J_{\beta}1-C_{\beta}1$ region of this phage is presented in Fig. 2a, and the nucleotide sequence of the C_B0 -hybridizing region is presented in Fig. 2b. The nucleotide sequence of the C_80 exon and its flanking introns closely match the consensus donor and acceptor splice sites established by Breathnach and Chambon¹⁵ (Fig. 2c), and the splice sites predicted by such an analysis are in complete agreement with the actual nucleotide sequences of the spliced C_{β} 0-containing cDNAs in Fig. 1. We conclude that the inclusion of the $C_{\beta}0$ exon in transcripts represents a naturally occurring alternative splicing pathway and is not an aberrant event or cloning artefact.

Thus far, $C_{\beta}0$ -containing clones have only been identified in cDNA libraries constructed from heterogeneous populations of T cells, such as from thymus or spleen, and not in libraries constructed from cloned T cells. From such data we cannot determine whether the 1.3% incidence of $C_{\beta}0$ expression seen in C57BL/6 spleen reflects a low level of alternatively spliced message in all $C_{\beta}1$ -expressing cells or if a particular subset of $C_{\beta}1$ -expressing cells selectively express $C_{\beta}0$ at higher levels. Two cDNA libraries we examined from cloned T cells both proved to have their V_{β} elements productively rearranged to $J_{\beta}2$ - $C_{\beta}2$ (ref. 10), and no $C_{\beta}0$ - or $C_{\beta}1$ -containing clones were obtained. Molecular analysis of several $C_{\beta}1$ -expressing T-cell clones have been reported $^{13,16-18}$, but no $C_{\beta}0$ -containing cDNAs were described in these reports. A thorough examination of

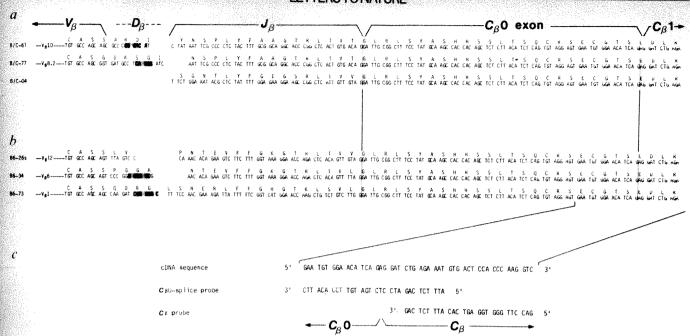

Fig. 1 Nucleotide and amino-acid (one-letter code) sequence of alternatively spliced TCR β -chain cDNAs. a, Isolates from BALB/c thymus. Clones containing a 72-bp insertion between the J_{β} and C_{β} elements are presented. Nucleotide and predicted amino-acid sequences begin at the 3' conserved cysteine codon of the V_{β} element and extend into the 5' end of C_{β} . Additional V_{β} or C_{β} sequence is not included as these sequences are well established $^{10-14,19}$; V_{β} gene segments are identified according to the nomenclature of Barth et al. a described in Behlke et al. Sequences contributed from the germline D_{β} 1.1 element are shaded while J_{β} gene segments are aligned separately. The J_{β} and C_{β} splice junctions are demarcated, and the 72-bp insertion has been labelled C_{β} 0. b, Isolates of three V_{β} -containing alternatively spliced cDNAs from C57BL/6 spleen. c, Design of C_{β} and C_{β} 0-specific synthetic oligonucleotide probes. The nucleotide sequences of alternatively spliced cDNA clones at the C_{β} 0- C_{β} splice junction are given, under which are aligned the sequences of two synthetic oligonucleotides which are complementary to the original cDNA sequence. The C_{β} 0-splice probe spans the C_{β} 0- C_{β} splice junction and is specific for clones in which the C_{β} 0 exon has been spliced to C_{β} . The C_{β} probe is complementary only to actual C_{β} coding sequence and hybridizes to all C_{β} -containing clones which extend sufficiently 5' to contain this sequence.

Methods. a, A BALB/c thymus cDNA library was screened with a TCR C_β-specific probe¹⁰. Random clones were subcloned into pUC12 and their nucleotide sequences were determined by the method of Maxam and Gilbert²⁵. b, A C57BL/6 spleen concanavalin A blast cDNA library (previously described¹⁰) was screened with a C_β0-specific oligonucleotide probe, as described below. C_β0-containing cDNAs were subcloned into pUC12 and their nucleotide sequences were determined by the method of Maxam and Gilbert²⁵. ³²P-labelled oligonucleotide probes were hybridized at 68 °C in 0.9 M NaCl, 0.18 M Tris pH 7.4, 0.012 M EDTA, 2× Denhardt's solution, and 20 μg ml⁻¹ salmon sperm DNA; washing was performed at 55 °C in 0.75 M NaCl, 0.075 M sodium citrate (5× SSC)²⁶.

several C_{β} 1-expressing T-cell clones for C_{β} 0 expression will be required to resolve this point.

The absence of $C_{\beta}0$ -like alternative splicing products in $C_{\beta}2$ containing transcripts can be explained in several ways. First, it may be that a $C_{\beta}0$ analogue $(C_{\beta}0')$ exists between the $J_{\beta}2$ cluster and C_{β} 2 but that this element has diverged far enough from the C_{β} 0 sequence described here so that our synthetic oligonucleotide probes do not cross-hybridize with it. Our first three $C_{\beta}0$ - $C_{\beta}1$ -containing clones were identified from an analysis of randomly isolated C_{β} -positive thymus cDNA clones (Fig. 1a). All subsequent C_{β} 0-containing clones were identified by hybridization to an oligonucleotide probe, which would select against the isolation of $C_{\beta}0'-C_{\beta}2$ -containing clones if this probe did not cross-hybridize to the putative $C_{\beta}0'$ sequence. A small number of C_{β} 2-containing clones have been examined for this possibility, and no $C_{\beta}0'-C_{\beta}2$ clones were found. While this may suggest that variable RNA splicing occurs exclusively in $C_{\beta}1$ transcripts, it is also possible that an insufficient number of $C_{B}2$ clones has been examined. However, we note that both nicktranslated and oligonucleotide probes specific for C_B0 do not hybridize to murine C_{β} 2-containing genomic clones (data not shown), and that no sequence with an open reading frame and >50% homology to C_8 0 can be found within 900 bp 5' of the first exon of C_{β} 2 (ref. 19).

It has been reported that the New Zealand White (NZW) mouse contains a germline deletion which includes both $C_{\beta}1$ and the $J_{\beta}2$ cluster⁸, suggesting that a $J_{\beta}1-C_{\beta}2$ -containing species should account for all NZW β -chain transcripts. The

deletion of $C_{\beta}1$ in the NZW mouse is thought to have resulted from a homologous recombination event between the first exon of $C_{\beta}1$ and the first exon of $C_{\beta}2$ (ref. 9). The sequence 5' to the single C_{β} coding region should therefore be of $C_{\beta}1$ origin, implying that the $C_{\beta}0$ exon will be present in NZW. To look for the existence of a $C_{\beta}0$ - $C_{\beta}2$ -containing species and examine $C_{\beta}0$ expression in the altered chromosomal context of the NZW mouse, an unamplified NZW thymus cDNA library was screened with the C_{β} and $C_{\beta}0$ -splice oligonucleotide probes. Of 146 C_{β} -positive clones identified, 26 hybridized to the $C_{\beta}0$ -splice probe. Thus, 18% (26/146) of the C_{β} -containing clones in the NZW thymus library use the $C_{\beta}0$ alternative splicing pathway. This frequency is significantly higher than the 1.3% level seen earlier in the C57BL/6 spleen cDNA library.

Two of these $26 C_{\beta}0$ -containing clones were randomly chosen for further analysis. The DNA sequences of these two clones were determined and are presented in Fig. 3. Clone NZW 8 is truncated within V_{β} coding sequence but was found to contain $V_{\beta}12-D_{\beta}1.1-J_{\beta}1.1-C_{\beta}0-C_{\beta}2$; clone NZW 22s is full-length and contains $V_{\beta}5.2-D_{\beta}1.1-J_{\beta}1.4-C_{\beta}0-C_{\beta}2$. While the $V_{\beta}12$ sequence seen in clone NZW 8 is identical to a V_{β} sequence reported previously 10, the V_{β} sequence in clone NZW 22s has not been reported; we note, however, that this sequence is 88% homologous at the nucleotide level to the published $V_{\beta}5.1$ sequence 3 and is therefore presumed to represent the second member of a three-member V_{β} gene subfamily, whose existence was inferred from Southern blot analysis using the $V_{\beta}5.1$ sequence as a probe 13 , 14.

Fig. 2 Genomic localization of the C_β0 exon. a, Restriction map locating C_β0 between J_β1 and C_β1. B, BamHI; R, EcoRI; K, Kpni; kb, kilobase. b, Nucleotide sequence of the C_β0 exon and flanking introns. Nucleotide sequence is given beginning at the EcoRI site, as shown c, Analysis of splice donor and acceptor sites. The nucleotide sequence of the C_β0 exon and its flanking introns is compared with the consensus donor and acceptor splice-site sequences reported by Breathnach and Chambon¹⁵. Py, pyrimidine; Pu, purine.
Methods. A BALB/c genomic library (EcoRI partial digest in Charon 4A, as described earlier²⁷) was screened with a C_β probe. Restriction maps of C_β-positive isolates were determined, and a clone was identified that was consistent with the map of the C_β1 locus reported earlier by Gascoigne et al. Exon elements were located by hybridization. For b, the 2.2 kb EcoRI fragment containing C_β0 and C_β1 was subcloned into pUC12 and the nucleotide sequence of the indicated region was determined by the method of Maxam and Gilbert²⁵.

GATTGC---CATCAGGTA

CAG

Expression of the $C_{\beta}0$ exon has been seen to vary from 1.3% of C_{β} -containing cDNA clones in a C57BL/6 spleen library to 18% of C_{β} -containing clones in an NZW thymus library. Direct comparison of the relative levels of $C_{\beta}0$ expression between these two libraries is difficult to interpret, however, because of uncertainty over the effects of the NZW $C_{\beta}1$ deletion on $C_{\beta}0$ expression. To better contrast the frequency of $C_{\beta}0$ expression between thymus and spleen, we constructed a C57BL/6 thymus cDNA library and screened a portion of the unamplified library with the C_{β} and $C_{\beta}0$ -splice oligonucleotide probes. Fourteen $C_{\beta}0$ -containing clones were identified from a total of 267 C_{β} -positives (Table 1). Thus 5% (14/267) of the C_{β} -containing clones in the C57BL/6 thymus library use the alternative splicing pathway.

Consensus splice sequence

Actual genomic sequence

C_B0-containing cDNA clones represent a species of mRNA that is expressed at levels ranging from 5% to 1.3% of total C_B-containing clones in our C57BL/6 thymus and spleen libraries, respectively. A lower level of $C_{\beta}0$ expression in spleen than in thymus could be specifically regulated, or it could simply parallel a lower level of overall $C_B 1$ usage in spleen. To address this possibility, the C57BL/6 thymus and spleen cDNA libraries were re-screened with probes specific for the 3'-untranslated sequence of $C_{\beta}1$ and $C_{\beta}2$; it was determined that $C_{\beta}1$ was present at levels of 32% and 27% of total C_{β} -positive clones in the thymus and spleen libraries, respectively (Table 1). The $C_{\beta}0$ element was present in 16% of thymic $C_{\beta}1$ clones and 5% of splenic $C_{\beta}1$ clones. No $C_{\beta}2$ clones were found to contain a C_{β} 0-hydrizing element. As the relative level of C_{β} 1 usage does not change significantly between thymus and spleen, the decrease in $C_{\beta}0$ usage may result from some kind of specific

down-regulation of this pathway independent of $C_{\beta}1$ usage in general.

Interestingly, this is not the first report of an alternative RNA splicing pathway in a T-cell-specific transcript. The murine Lyt 2 gene has been shown to produce two species of mRNA via alternative splicing²⁰. The relative proportions of the two mRNA species were seen to differ between thymus and spleen; in parallel with our observations of alternative splicing in TCR β -chain, expression of the minor species of Lyt 2 mRNA was seen to be higher in thymus than in spleen.

Insertion of the $C_{\beta}0$ exon between a J_{β} element and the C_{β} element maintains the expected J_{β} - C_{β} translational reading frame, and the new exon itself encodes a 24-codon open reading frame. Thus, there is no obvious reason to suspect that $C_{\beta}0$ -containing β -chain transcripts should not be translated in parallel with other C_{β} -containing transcripts. While we have no data directly demonstrating the existence of a $C_{\beta}0$ -containing protein species, it seems reasonable to propose that such a species should actually exist, leading to the prediction that, in some circumstances, surface TCR could be a mixed population composed of both $C_{\beta}0$ -containing and $C_{\beta}0$ -excluding β -chain peptides.

Some predictions can be made from the primary sequence of the new exon regarding the potential effects its insertion may have on β -chain protein structure. The translated amino-acid sequences from Fig. 1 were analysed using the algorithm of Chou and Fasman²¹. The C_{β} 0 sequence was found to occupy a region of low β -sheet and α -helix potentials with moderate reverse-turn probability, leading to a composite prediction of a random-turn secondary structure throughout this region. Inter-

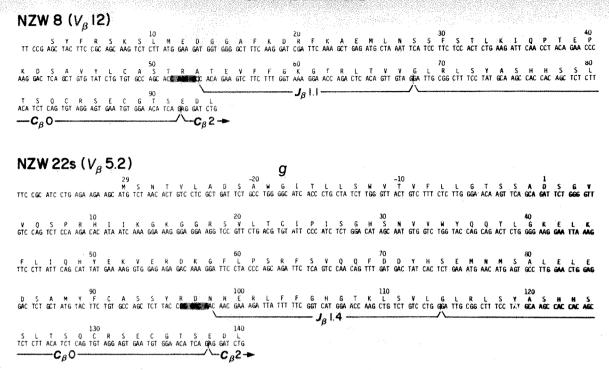

Fig. 3 Nucleotide and amino-acid sequences of the V-D-J regions from two C_{β} 0-containing isolates from an NZW thymus cDNA library. Sequences contributed from germline D_{β} 1.1 are shaded, while I_{β} , C_{β} 0 and C_{β} 2 gene segments are underlined. Nucleotides between D_{β} and J_{β} segments are proposed N-region insertions. The cDNA library was constructed from oligo(dT)-cellulose-selected NZW thymus RNA²⁶ in the λ gt10 cloning vector as described by Huynh et al.²⁸, with modifications²⁹. Library screening was done with ³²P-labelled oligonucleotide probes as described for Fig. 1c; C_{β} 0-positive clones were subcloned into pUC12 and their DNA sequences determined by the method of Maxam and Gilbert²⁵.

estingly, these parameters are very similar to those generated for the hinge region of human $\gamma 1$ immunoglobulins (data not shown). In addition, the $C_{\beta}0$ sequence contains two nearly adjacent cysteine residues in a region predicted to be hydrophilic by the algorithm of Hopp and Woods²². If these residues do not bond to each other, they may be available to form inter- or intra-chain disulphide bonds not usually present in the β -chain peptide. It is interesting to speculate that the presence of this sequence promotes the association of β -chain with a peptide other than α -chain (for example, γ -chain).

While it is not clear whether the $C_{\beta}0$ exon actually has any functional significance in vivo, it may be relevant to note that $C_{\beta}0$ is expressed at a fourfold higher level in thymus than in spleen. Decreased peripheral expression might simply reflect that few C_B 0-expressing T cells escape the thymus to become splenic T cells. Alternatively, it might reflect specific downregulation of the C_{β} 0 splicing pathway as cells leave the thymus. In regard to developmental regulation, we note that most $C_{\beta}0$ containing cDNAs isolated from thymus are also V_{β} -containing,

suggesting that the more immature thymic 'D-J' type transcripts²³ may express the C_B0 exon at lower levels than mature V-D-J transcripts. The thymus cDNA libraries examined here were constructed from tissue obtained from 6-week-old animals; it would be interesting to see whether the frequency of $C_{\beta}0$ expression varies with the developmental stage of the thymus. Further, we do not know whether the $C_{\beta}0$ splicing pathway is unique to the murine system or if it is also available to human TCR β -chain transcripts. In this regard, we note that no sequence with recognizable homology to $C_{\beta}0$ is present in the published human $C_{\beta}1$ sequence²⁴, although only a small portion of the intron between the $J_{B}1$ cluster and $C_{B}1$ has been reported.

Synergism between immunoglobulin enhancers and promoters

J. Victor Garcia, Lê thi Bich-Thuy, Jeannine Stafford & Cary Queen

Laboratory of Biochemistry, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20892, USA

Enhancers are DNA sequences that stimulate transcription from eukaryotic promoters1-3. This stimulatory effect can be exerted over large distances and from a position either 5' or 3' of a promoter. Enhancers have been found in the genomes of many viruses, and in some cellular genes such as those encoding immunoglobulin heavy chain^{4,5} and κ light chain^{6,8}. An important feature of both viral and cellular enhancers is the ability of each enhancer to stimulate transcription from many promoters other than the one with which it is found associated1,2. However, the question of whether cellular enhancers stimulate their 'own' promoter more efficiently than other promoters has apparently not been investigated. We show here that the k light-chain enhancer stimulates a k promoter about 20-fold more than it stimulates either the simian virus 40 (SV40) early promoter or a metallothionein (MT) promoter, two promoters that are very sensitive to other enhancers. Similarly, the heavy-chain enhancer stimulates a heavy-chain promoter much more than it stimulates the SV40 and MT promoters. This synergism between immunoglobulin enhancers and promoters might be due to the action of a protein that binds specifically to each of the regulatory elements.

To measure the effects of different enhancers, we used the chloramphenicol acetyltransferase (CAT) assay9, which has been widely employed for that purpose (see, for example, refs 10, 11). Four sets of plasmids were constructed. Plasmids used to determine the effect of enhancers on the SV40 early promoter were derived from pA10cat2 (ref. 10) which here is called pAcat (Fig. 1a). To determine the effect of enhancers on a κ gene promoter from the mouse myeloma MOPC 41 (ref. 12) we constructed the plasmid pKcat (Fig. 1b); in this plasmid, a fragment extending from an EcoRI site about 1,100 base pairs (bp) before the κ transcription start site to 25 bp beyond the start site was connected to the cat gene via a BglII adapter. Similarly, a fragment of the mouse 17.2.25 heavy-chain gene 13,14 extending from ~2,000 bp before the promoter start site to 44 bp beyond the start site, was connected to the cat gene to form the plasmid pHcat. These plasmids also include the origin of replication of SV40 (ori), without the SV40 enhancer, in order to make them more analogous to pAcat (Fig. 1). Finally, the effect of enhancers on the mouse metallothionein-I (MT-I) promoter was determined using the plasmid pMcat. This plasmid is similar to pKcat and pHcat, except that the immunoglobulin gene segments are replaced by a fragment extending from an EcoRI site ~1,900 bp before the transcription start site of the MT gene to a BglII site located 64 bp after the start site 15. On all plasmids, the initiating ATG of the cat gene is the first ATG codon after the expected transcription start site.

Three DNA fragments containing known enhancers from murine viruses or genes were inserted into each of the plasmids pAcat, pKcat, pHcat and pMcat at the sites indicated in Fig. 1. The polyomavirus and κ light-chain gene enhancers were, respectively, contained on the 238-bp and 473-bp fragments used previously 16, and the heavy-chain enhancer was contained on a 682-bp XbaI-EcoRI fragment 4.5. The enhancers were inserted in the same orientation with respect to the direction of cat transcription that they have relative to the polyoma Tantigen, κ and heavy-chain genes. Plasmids containing the polyoma virus, κ and heavy-chain enhancers are designated with the suffixes P, K and H, respectively. All transfection experiments were performed on S194 cells (ATCC TIB 19), a mouse

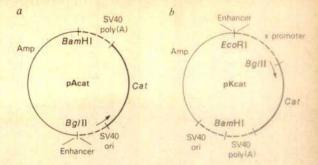

Fig. 1 Schematic diagrams of plasmids (not to scale). Arrows indicate the approximate initiation sites and direction of transcription from the SV40 early and κ promoters. Enhancers were inserted by means of Bg/II linkers into pAcat and by EcoRI linkers into pKcat. a, pAcat is the plasmid pAl0cat2 of ref. 10, and does not contain the SV40 enhancer. b, The part of pKcat from the EcoRI site counterclockwise to the BamHI site was taken from pLT1 (ref. 6), and the part from the Bg/II site to the BamHI site is the HindIII-BamHI fragment of pSV2cat9. The plasmids pHcat and pMcat are similar to pKcat, with the κ gene segment replaced by heavy-chain and MT gene segments, respectively. Plasmids were constructed by standard methods; details available on request.

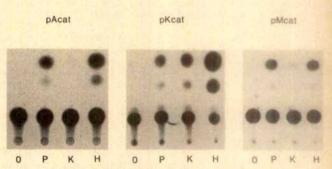

Fig. 2 CAT assays of extracts from transfected cells. The cells were transfected with the indicated plasmids containing the enhancers noted beneath the lanes: 0 (no enhancer), P (polyoma), K (κ) and H (heavy chain).

Methods. For each plasmid, one plate containing ~10⁷ S194 cells was transfected as described elsewhere⁸, except that the transfection was done in 1 ml with 5 μg DNA. After 24 h, an additional 15 ml of medium was added to each plate, and CdCl₂ to 6 μM was added to the cells transfected with the pMcat plasmids. Cells were harvested after another 24 h and CAT assays performed as described elsewhere⁹, using half of the extract from each plate and a 1-h incubation.

immunoglobulin (α, κ) myeloma line that we have found to have high transfection efficiency (unpublished data).

The plasmid pAcat and derivatives were transfected in parallel into S194 cells. After 48 h, the cells were lysed and tested for CAT activity9; Fig 2 shows the results of a typical experiment. The geometric means of the determinations of per cent 14Cchloramphenicol conversion for three separate experiments, using two sets of independently isolated plasmids, are shown in Table 1; all numbers have been normalized to the values for pAcatP rather than for pAcat, because the values for the latter are much smaller and may therefore be less reliable. Insertion of the k enhancer into pAcat led to only a 4.2-fold increase (0.008 to 0.034) in transcription of cat, as measured by CAT synthesis, while the polyoma and heavy-chain enhancers respectively produced increases of 125- and 236-fold. These results are consistent with the finding that the k enhancer is only 5% as effective as the heavy-chain enhancer in stimulating a β-globin promoter7. Two additional plasmids, identical to pAcatK and pAcatH except with the orientations of the enhancer fragments reversed, were transfected at the same time as the other plasmids,

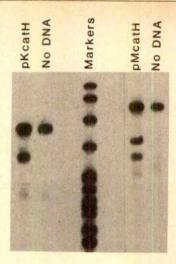

Fig. 3 S₁-nuclease assay of RNAs from transfected cells. S194 cells were transfected with the indicated plasmids, containing the polyoma early region, or were mock-transfected without DNA. After 48 h, total RNA was extracted from the cells and assayed as described elsewhere. The topmost band in each lane ran at the position of intact probe. The markers were an *Hpa*II digest of pBR322; sizes (in nucleotides) were: 622, 527, 404, 309, 242, 238, 217, 201, 190, 180, 160 and 147.

and yielded mean normalized CAT values of 0.038 and 0.70, respectively. Thus, reversing the orientation had no significant effect on the κ enhancer while it reduced the effect of the heavy-chain enhancer by a factor of \sim 3.

Corresponding data were obtained for the plasmid pKcat, in which the κ promoter is linked to the cat gene (Fig. 2, Table 1). In contrast to the pAcat results, the κ enhancer stimulated transcription of the cat gene on pKcat more than did the polyoma enhancer, and the heavy-chain enhancer stimulated cat transcription by much more. In fact, the κ enhancer and the heavy-chain enhancer increased CAT synthesis by 88-fold (0.017 to 1.49) and 829-fold, respectively. Hence, the κ enhancer apparently stimulated transcription from the κ promoter about 20 times more efficiently than from the SV40 promoter, and the heavy-chain enhancer stimulated κ transcription about four times more than SV40 transcription. These results cannot be caused by the κ promoter being generally more sensitive to enhancers than the SV40 promoter, because the polyoma enhancer stimulated the κ promoter less than it did the SV40 promoter.

However, to verify that the phenomenon was not caused by a pecularity of the SV40 promoter, we used pMcat, a plasmid very similar to pKcat in which a metallothionein promoter replaces the κ promoter. 24 h after transfection of pMcat and its derivatives into S194 cells, cadmium was added to the medium to induce the MT promoter. The results (Fig. 2, Table 1) were analogous to those for the pAcat plasmids. In fact, the κ en-

Table 1 Effect of enhancers on different promoters

Enhancer	Plasmid					
	pAcat	pKcat	pMcat	pHcat		
None	0.008	0.017	0.041	< 0.01		
Polyoma	1.00	1.00	1.00	1.00		
K	0.034	1.49	0.19	0.58		
Heavy chain	1.89	14.1	0.92	15.3		

Each value is the geometric mean of determinations of per cent chloramphenical conversion after three independent transfections, and is normalized to the values for the polyoma enhancer. hancer stimulated transcription from the MT promoter only 4.6-fold, again about 20-fold less than from the κ promoter. Similarly, the heavy-chain enhancer increased transcription from the MT promoter much less than from the κ promoter. When cadmium was omitted from the medium, the amount of CAT synthesis from all the pMcat plasmids was decreased about fivefold, so that the amount of stimulation by the various enhancers remained approximately the same.

Finally, data were obtained from the pHcat plasmids, which have the heavy-chain promoter linked to cat (Table 1). The plasmid pHcat itself, which has no enhancer, expressed CAT at a very low level, precluding its accurate quantification. Moreover, whereas the heavy-chain enhancer stimulated the SV40 and MT promoters about as well as did the polyoma enhancer (Table 1), the heavy-chain enhancer stimulated the heavy-chain promoter 15.3 times more than did the polyoma enhancer. This result and the low level of heavy-chain promoter activity without any enhancer imply an especially effective interaction between the heavy-chain promoter and enhancer. Relative to the polyoma enhancer, the k enhancer stimulated the heavychain promoter more (0.58) than it stimulated the SV40 or MT promoters (0.034 and 0.19) but less than it stimulated the κ promoter (1.49). Taking all the data together, the strongest synergism exists between the k enhancer and promoter and between the heavy-chain enhancer and promoter, but there is also synergism between any pair of immunoglobulin gene elements.

Our results were not affected by fluctuations in transfection efficiency of the plasmids into the S194 myeloma cells. Indeed, each set of plasmids was independently transfected in parallel three times. The multiplicative standard deviations¹⁷ of the values for each plasmid were less than 1.6, except for pKcatH (1.82). In other experiments, the pKcat and pMcat plasmids were mixed with the plasmid pCH110, which contains a gene for β -galactosidase¹⁸, before transfection. Extracts of the transfected cells were assayed for both CAT and β -galactosidase activity. The β-galactosidase values for the four pKcat plasmids had a multiplicative standard deviation of only 1.02, and for the pMcat plasmids only 1.06. Hence, the transfection efficiencies for the plasmids within each experiment were very similar. Moreover, after normalization to the results for pKcatP and pMcatP, the CAT values for the plasmids carrying the k and heavy-chain enhancers showed no significant differences from the values in Table 1.

Many studies have shown that enhancers do not alter the start point of transcription from the promoters that they stimulate (see, for example, refs 1, 4, 19). In particular, we have shown that in lymphoid cells, transcription initiates from the same place in the κ promoter when it is stimulated by either the κ or polyoma enhancers 16. To further verify the location of the transcription start sites in the experiments presented here, we extracted RNA from S194 cells 48 h after they had been transfected with pKcatH or pMcatH. The RNAs were analysed using an S₁-nuclease assay, with double-stranded probes labelled at the EcoRI site in the cat gene 9, and respectively extending to the MaeIII site 5' of the κ promoter 20 or to the SacI site 5' of the MT promoter 15. In initial S₁ experiments, no signals were detected clearly from pKcatH or pMcatH, probably because of instability of the cat RNA.

To increase the signal, we inserted the polyoma early region into pKcatH and pMcatH. This region has been shown to increase the amount of RNA transcribed from transfected plasmids by allowing them to replicate in mouse cells, thus increasing the amount of DNA template 6,8,21 . The S_1 analysis of RNA from cells transfected with the modified pKcatH plasmid (Fig. 3) revealed a strong band of a length corresponding to transcripts from the usual κ start site 6 . The RNA from cells transfected with the modified pMcatH plasmid yielded two bands (in addition to residual intact probe): the length of the stronger, upper band corresponds to transcripts from the usual MT start site 15 ;

the lower band presumably represents transcripts initiating ~40 bp farther downstream. Both bands were also present when the MT promoter was stimulated by the polyoma enhancer in pMcatP, but were much weaker when there was no enhancer present on the plasmid (not shown). The shorter transcript from the MT promoter has not been observed previously¹⁵, but the probe used in that study would probably not have detected it.

An attractive explanation for the observed synergism between immunoglobulin enhancers and promoters is that one or more proteins specifically bind to all of these regulatory regions. The existence of such proteins might be reflected in sequence homologies between the regulatory regions. Such homologies

have indeed been observed²². Recently, direct evidence of a protein that binds both immunoglobulin promoters and enhancers has been obtained²³. The results presented here may help to explain the negative findings of searches for cellular enhancers that use a heterologous promoter as the assay24. Many enhancers in cellular genes may, like the k enhancer, efficiently stimulate only their own or related promoters.

We thank L. Laimins, F. Lee and D. Hamer for providing pAcat, pCH110 and the MT promoter, respectively. We thank C. Mock and B. Miller for photographic and sectarial assistance. and M. Singer for reviewing the manuscript. L.T.B.-T. was partially supported by INSERM, France.

University of Toronto, Toronto, Ontario, Canada M4X 1K9

Adenosine deaminase (ADA) deficiency, an autosomal recessive inborn error of metabolism, leads to severe combined immune deficiency in man1. This enzyme, although constitutively expressed in most tissues, is expressed at high level in immature T cells, and study of the pathophysiology of the disorder indicates that increased deoxyadenosine or altered methylation capacity have toxic effects on T-cell maturation1. Although bone marrow transplantation can correct the immune deficiency^{2,3}, this therapy is associated with graft-versus-host disease and incomplete immune restoration, and so our laboratory and others have sought to develop a method of gene replacement as a possible treatment for the disease4. Moreover, characterization of the complementary DNA of the human ADA gene and some of its mutants^{5,6} makes it possible to design gene transfer strategies. We have now subcloned a human adenosine deaminase cDNA into the retrovirus shuttle vector pZIP-SV(B), and in this way have isolated a cell line, 4.2T, which produces high titres of replication-defective retrovirus which have been used to transfer the gene for human ADA to mouse bone marrow cells. Transfer and expression of the neomycin-resistance gene (neo) and the ADA gene in murine bone marrow colony-forming units (CFU) was demonstrated by in vitro colony formation in the presence of the antibiotic G418 or 9xylofuranosyladenine plus deoxycoformycin, respectively. Isoenzyme analysis also showed human ADA expression in the cultured mouse bone marrow.

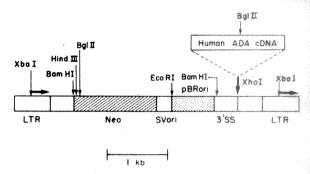

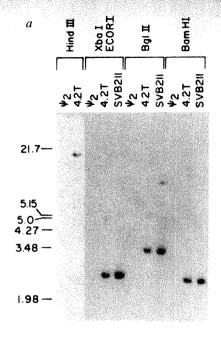

Fig. 1 Construction of the 4.2T cell line. The SV(B) plasmid vector was cleaved with XhoI, filled in with Klenow and treated with calf intestinal phosphatase (CIP). The pADA2115 plasmid containing a full-length human ADA cDNA was cleaved with EcoRI and DdeI, thus removing the 3' poly(A) addition site, filled in with Klenow and blunt-end ligated to the SV(B) vector. The SVBADA211 plasmid was isolated by banding in CsCl, and 10 µg purified DNA was used to transform PA-12 (ref. 9) cells by CaPO_a precipitation. Supernatant from these cells, containing the transiently expressed SVBADA211 virus with an amphotropic envelope, was collected at 48 h and used to infect ψ_2 cells. These cells were placed in Dulbecco's modified Eagle's medium (DMEM) with 10% FCS containing G418 (300 µg mf⁻¹). Ninetysix G418-resistant clones were selected and placed in 11AAU (1.1 mM adenosine, 50 mM alanosine, 1.0 mM uridine) plus 50 nM deoxycoformycin (dCf). Two cell lines, 4.1T and 4.2T, were able to grow in this selective medium, and 4.2T had both higher expression of human ADA and higher titre virus production. LTR, long terminal repeat. SVori, SV40 origin of replication; pBRori, origin of replication from pBR322; 3'SS, 3' splice site; kb, kilobases.

The development of a biological gene transfer system based on highly infectious retroviruses opens the way to efficiently introducing genes into rare cell populations⁷⁻¹⁰, and several studies have recently demonstrated that the neo gene can be transferred into murine haematopoietic progenitors and stem cells using retroviral vectors¹¹⁻¹⁵. However, ADA gene transfer is hampered by the need to fulfil several requirements: (1) the production of a high-titre ADA vector without concomitant production of replication-competent virus, (2) expression of the transferred ADA gene in the target cells (that is, in marrow stem cells and their differentiated progeny), and (3) adequate expression at the tissue level in the test animal (ADA in thymus

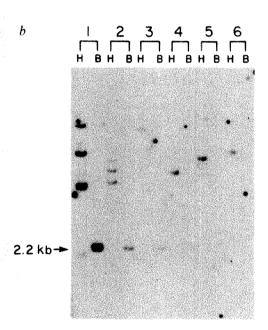

Fig. 2 a, Southern analysis of 4.2T. b, Southern analysis of 4.2T-infected cells. H, digestion with *HindIII*; B, digestion with *Bam* I. Lanes 1-6 represent individual clonal cell lines.

Methods. a, Genomic DNA was prepared from cultured ψ_2 and 4.2T cells by standard techniques. 10 µg of genomic DNA or 40 pg of plasmid was digested overnight with the indicated restriction enzymes, separated on 0.8% agarose, Tris-acetate-EDTA buffered gel at 40 V for 16 h. The gels were blotted onto nylon membrane, prehybridized overnight and probed with nick-translated neo insert at 42 °C with 50% formamide. The filters were washed in 0.1 × SSC at 60 °C and then autoradiographed overnight. b, NIH 3T3 cells were infected with supernatants from 4.2T. After 48 h the cells were placed in DMEM with 300 µg ml⁻¹ G418. The surviving cells were clonally selected and grown in DMEM plus G418. Genomic DNA was extracted, digested with either HindIII (H) or BamHI (B). Filter hybridization with ³²P-neo was as described in A. Cell lines with apparent multiple inserts (lanes 1, 2) are being recloned to establish homogeneity.

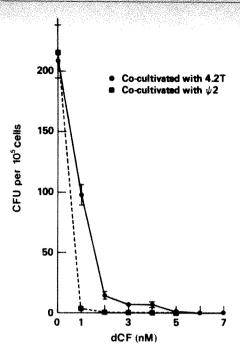

Fig. 3 Selection of CFU for ADA expression. Co-cultivation of 4.2T and mouse marrow cells was identical with that described in Table 1. After 24 h co-cultivation, the non-adherent cells were collected and plated in IMDM with 1% methylcellulose cultures with 5 μ M XylA and varying concentrations of dCF. CFU were counted at 7 days. Data represent averages of duplicate culture from two separate experiments $\pm\,s.e.m.$

and spleen). The present experiments investigated these problems in committed bone marrow progenitor cells. The vector pZIP-SV(B)10 (Fig. 1) was chosen because it allows the neo gene to be used as a dominant selectable marker for expression. The cell line 4.2T was formed by infection of the ψ_2 packaging line by defective amphotropic SVBADA211 virus. This line was clonally isolated after sequential selection in G418¹⁶ and then 11AAU (1.1 mM adenosine, 50 mM alanosine, 1.0 mM uridine) plus 50 nM deoxycoformycin (dCF)¹⁷. These selections require expression of neomycin phosphotransferase and increased ADA expression. The amount of dCF added makes the selection very stringent and thus rapidly identifies cells showing maximal expression of the transferred ADA gene. Of 96 G418-resistant isolates screened in this way, the 4.2T line had the highest expression of human ADA. The titre on NIH 3T3 mouse fibroblasts is $\sim 2 \times 10^4$ CFU per ml (G418 resistance). Southern analysis of 4.2T (Fig. 2a) indicated that the cell line has a single proviral insert. In addition, the 4.2T provirus was identical with plasmid pSVBADA211 using several internal restriction cuts, indicating that the selection procedure did not engender a gross rearrangement of the provirus. Southern analysis of cell lines infected with virus produced by 4.2T showed intact internal provirus structure (Fig. 2b). This also strongly suggests that the basic transcriptional unit of the provirus was not altered during selection. A more subtle alteration—for example, point mutations-cannot be ruled out, however.

The 4.2T cell line was then used to test the transfer and expression of the *neo* and ADA genes in murine haematopoietic cells. Mouse bone marrow was co-cultivated with 4.2T cells for 24 h according to the protocol of Dick *et al.*¹³. Non-adherent cells were replated in liquid media for 48 h with or without preselection in G418. These cells were then replated in semisolid media in the absence or presence of G418 to determine the proportion of resistant CFU. Table 1 indicates that approximately 10% of CFU acquire G418 resistance when co-cultivated with 4.2T. Co-cultivation with ψ_2 gives no G418-resistant colonies, indicating the specificity of the effect. Metabolic selec-

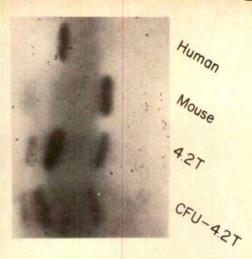

Fig. 4 Isoenzyme analysis of ADA in G418-selected infected bone marrow cells. Lane 1, HeLa cell (human) extract; lane 2, ψ2 cell (mouse) extract; lane 3, 4.2T; lane 4, CFU co-cultivated with 4.2T cells. The infection of mouse bone marrow cells was identical with that described in Table 1 except that the 4.2T cells were irradiated (1,500R, Gamma-cell 100, 137Cs source) before co-cultivation. Cells from CFU cultures were collected by repeated washing to remove the methylcellulose. Cell extracts were made by freezing and thawing in 20 mM Tris-HCl, pH 7.5. Supernatants were cleared by 15 min spin in a microcentrifuge. Cell extracts were loaded on a prefocused 1-mm-thick pH 4-5 polyacrylamide isoelectric focusing gel. Focusing was stopped after 3-4 h and the gel was soaked in 50 mM Tris-HCl pH 8.0 for 20 min. The gel was then stained for ADA enzyme activity using an agar overlay by standard methods17.

tion of CFU for increased expression of ADA was also performed using 9-xylofuranosyl adenine (XylA) plus dCF18 in a similar protocol (Fig. 3). XylA plus dCF was used for ADA selection because it gives a sharper inflection on survival curves than 11AAU for both fibroblasts and CFU. These data show a preferential survival of CFU co-cultivated with 4.2T compared with those co-cultivated with ψ_2 . At medium concentrations of dCF (2-4 nM), the per cent resistant CFU was comparable to the results obtained with G418 selection. To confirm the expression of human ADA in these cultured marrow cells, the cells were pooled from G418-selected cultures, and freeze-thaw extracts were prepared and run on an isoelectric focusing gel (Fig. 4). A band corresponding to the human ADA was detected only in CFU arising from 4.2T-infected marrow. Carryover of human enzyme activity from 4.2T virus-producer cells is highly unlikely since the monolayer was irradiated and there were two rounds of removal of adherent cells before replating in semisolid media. However, we cannot rule out a contribution to the observed expression by more mature non-colony-forming marrow cells.

These preliminary studies show that by exploiting the selectability of the ADA gene, cell lines producing high-titre retrovirus can be rapidly selected. The endogenous ADA gene can be amplified using 11AAU plus dCF¹⁷, and it may therefore be possible to increase virus production by amplification of the ADA-containing provirus. We have also shown that this particular SV(B)-human ADA construction is expressed well in murine haematopoietic cells after infection in vitro. There are several reports indicating problems with expression in retroviral constructs containing two genes^{19,20}. Furthermore, expression of a particular retroviral construct in mature marrow cells and committed progenitors does not guarantee that the same retroviral vector will function well after infection of more primitive stem cells. Indeed, preliminary data indicate significant loss of expression of neo in the differentiated progeny of infected CFU (ref. 21 and J.E.D. et al., manuscript in preparation). It is generally considered that constructs that use separate promoters

Table 1 Selection of CFU for neo expression

Preselection	Selection	ψ_2	4.2T
_	_	240 ± 26	218 ± 20
_	G418	0	24±5
G418	-	0	19±5
G418	G418	0	7±2

 ψ_2 or 4.2T cells (1×10⁶) were plated in 100-mm tissue culture dishes (Corning) in Iscove's modified Dulbecco's medium (IMDM, Gibco) with 25% fetal calf serum (FCS). The next day 4×106 bone marrow cells from the tibias and femurs of C3H/HeJ or C57B16/J (Jackson Laboratories) were placed in each dish in IMDM supplemented with bovine serum albumin (BSA), soybean lipid, Fe-saturated transferrin (Boehringer Mannheim), penicillin-streptomycin (Gibco), 10% FCS, 10% WEHI3B-conditioned medium, α-thioglycerol and 2 μg ml-1 Polybrene (Sigma). Twenty-four hours later, non-adherent cells were washed off and plated in fresh 100-mm Petri dishes (Falcon) with or without selective drugs (preselection). After 48 h recovery, the non-adherent cells were again collected, counted and 1×105 cells were plated in 1 ml IMDM with 1% methylcellulose (Fluka). These cultures had either no drug selection, or 1 mg ml⁻¹ G418. CFU (>200 cells) were counted 7-10 days after initiation of the semisolid cultures. Data are expressed as averages of three separate experiments ±s.e.m.

for each cDNA (two transcriptional units) give better expression in target cells. The SV(B) construction used here has only one transcriptional unit. We presume that expression in the target cell is dependent on the particular features of each construction and that it is premature to predict how a construction will behave at the stages of virus production and target cell expression. Other constructs using both double-promoter and unspliced designs are under investigation in our laboratory.

Somatic gene transfer techniques may allow a number of difficult biological problems to be addressed. Several reports indicate its usefulness in investigating cell lineage relationships in the haematopoietic system 13,14, and similar hierarchy studies may be undertaken with other tissues if infection is carried out at multiple developmental stages. Retrovirus gene transfer may also be useful for the study of oncogenesis22,23, while transfer of poorly understood genes into haematopoietic cells (for example, T1a or T11 antigen) may help to clarify their functional role. Finally, this technique may allow safe and effective treatment of ADA deficiency and various other inborn errors of metabolism by somatic gene therapy.

The alternative nitrogenase of Azotobacter chroococcum is a vanadium enzyme

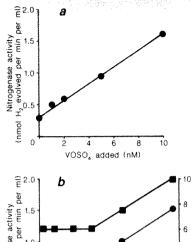

Robert L. Robson, Robert R. Eady, Toby H. Richardson, Richard W. Miller*, Marie Hawkins & John R. Postgate

AFRC Unit of Nitrogen Fixation, University of Sussex, Brighton BN1 9RQ, UK * Chemistry and Biology Research Institute, Agriculture Canada, Ottawa, Canada K1A 0C6

The requirement for molybdenum in biological dinitrogen fixation, first reported by Bortels1, is due to its involvement at or near the site of reduction of N₂ in conventional nitrogenase. To date, all nitrogenases which have been purified to homogeneity consist of an iron protein (component 2) and a molybdoprotein (component 1)2. Azotobacter vinelandii, an obligately aerobic diazotrophic bacterium, has two systems for nitrogen fixation: a conventional nitrogenase involving molybdenum and an alternative system which functions under conditions of Mo deficiency and does not require the structural genes for conventional nitrogenase3-6. The properties of the nitrogenase in extracts of comparable deletion strains of A. vinelandii are consistent with a two-component system^{6,7} in which the component 1-containing fraction has no detectable Mo (ref. 6). Recently, an alternative nitrogen fixation system has been demonstrated in Azotobacter chroococcum strain MCD1155, in which the structural genes for conventional nitrogenase are deleted8. We demonstrate here that nitrogen fixation by this strain depends on vanadium and we show that its purified nitrogenase is a binary system in which the conventional molybdoprotein is replaced by a vanadoprotein.

A. chroococcum NCIMB 8003 contains conventional nitrogenase when grown diazotrophically in a medium containing molybdate⁹. The genes which encode the polypeptides for this nitrogenase (nifH for the Fe-protein, Ac2; nifD and nifK for the α and β subunits of the MoFe-protein, Ac1) have been cloned as a contiguous cluster from this organism¹⁰. Strains in which this gene cluster was deleted, constructed by a genereplacement technique, were incapable of N₂ fixation when molybdate was provided, but developed feeble acetylene reduction activity indicative of nitrogenase in Mo-deficient medium8. A derivative, MCD1155, defective in uptake hydrogenase activity and resistant to up to 5 mM sodium tungstate (an inhibitor of molybdate uptake or assimilation in azotobacter^{11,12}), grew in N₂, and exhibited ¹⁵N incorporation from ¹⁵N₂, acetylene reduction and nitrogenase-dependent H₂ evolution. Growth and nitrogenase activity in MCD1155 apparently required relatively high (2.5 mM) concentrations of sodium tungstate8.

The most probable reason for so high a tungstate requirement is that our tungstate was contaminated with traces of an element (or elements) required for diazotrophy in this strain, We therefore tested cultures which grew poorly, in the N-deficient, Modeficient medium of Fig. 1, for stimulation of growth by Na₂SeO₃ $(29 \mu M)$, MnCl₂ $(15.2 \mu M)$, CuSO₄ $(0.6 \mu M)$, NiCl₂ $(0.2 \mu M)$, CoCl₂ (5 µM), FeSO₄ (50 µM), ZnSO₄ (7 µM), CaCl₂ (100 µM), Na_2MoO_4 (10 nM or 100 μ M), Na_3BO_3 (81 μ M) or $NaReO_4$ (10 μM). None stimulated growth. However, VOSO₄ at low concentrations restored growth; Fig. 1a shows that nitrogenase activity as measured by H2 evolution was proportional to added VOSO4 between 1 and 10 nM. From these data we deduced a specific activity for H₂ evolution in air of 120 pmol per min per pg atoms V. Mo, V-starved organisms responded rapidly and in a biphasic pattern to V (Fig. 1b); a rapid two fold activation of hydrogen-evolving activity seen after 30 min was followed by a slower progressive increase in activity over 10 h. Growth was evident after 6 h. We conclude that vanadium is required for diazotrophic growth of this strain.

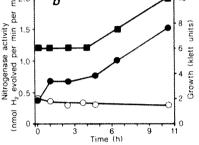

Fig. 1 Influence of vanadium on diazotrophic growth and nitrogenase activity in A. chroococcum MCD1155. a, Organisms were inoculated to 5×10^6 cells ml $^{-1}$. VOSO $_4$ was added and nitrogenase activities were measured in cultures by following H $_2$ evolution. Maximum activities obtained after 48 h at 30 °C are plotted. b, Organisms were inoculated to 5×10^7 ml $^{-1}$. At time zero, VOSO $_4$ was added to 10 nM. Nitrogenase activity was determined at intervals by following H $_2$ evolution over 15 min. Growth was determined using a Klett-Summerson photoelectric colorimeter and is shown for the V-supplemented culture only (\blacksquare). No growth was observed without added V. \blacksquare , Nitrogenase activity with V added; \bigcirc , without V added.

Methods. A. chroococcum MCD1155 was routinely grown in air at 30 °C in (g per l of distilled H_2O): sucrose 20; $K_2HPO_4 \cdot 3H_2O$, 0.64; KH_2PO_4 , 0.16; Na_2SO_4 , 0.142; $MgCl_2 \cdot 6H_2O$, 0.203; $CaCl_2 \cdot 2H_2O$, 0.074; $FeC_6H_5O_7$, 0.0335; Na_2WO_4 , 0.734. To test for the influence of V on growth and nitrogenase activity, organisms were grown without added tungstate until residual level was

The apparent requirements for high levels of tungstate could have been due to: (1) competitive exclusion of traces of molybdenum, (2) use of W in place of V via an inefficient uptake system or (3) contamination of our tungstate source with traces of V. We eliminate possibility (1) because, in shaken flasks with the Mo-free medium, diazotrophic growth of MCD1155 depended on tungstate concentration up to 2.5 mM, but addition of normal levels of molybdate (100 µM) to cultures containing 2.5 mM tungstate did not inhibit growth. Our studies do not conclusively eliminate explanation (2), but we favour explanation (3) because we have detected trace contamination (22 p.p.m. V) of our tungstate source and, in the presence of 2.5 mM tungstate, added vanadium did not stimulate growth.

Nitrogenase activity in extracts of MCD1155 prepared as in Fig. 2 had properties and requirements similar to those of conventional nitrogenases. Activity measurable as H₂ evolution, acetylene reduction or ammonia production was ATP- and reductant-dependent (data not shown). The activity was highly sensitive to irreversible inactivation by O₂, unlike the enzyme in crude extracts of the parent strain grown in molybdenum-sufficient conditions.

MCD1155 nitrogenase was purified essentially as described in Fig. 2 legend. Two readily separable yellow-brown coloured protein components were purified to homogeneity by a combination of ion-exchange and gel-filtration chromatography (Fig. 2). Both proteins were essential for activity. We refer to these

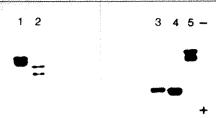

Fig. 2 Polyacrylamide gel electrophoresis of nitrogenase components of A. chroococcum MCD1155. Lanes 1 and 5, Acl 2.9 μg and 2.9 μg, respectively; lane 2, Acl* 2 μg; lane 3, Ac2* 11.0 μg; lane 4, Ac2 2.7 μg.

Methods. Organisms were grown in 400 l of the medium described in Fig. 1 legend with 40 µM VOSO4 added. Cells were collected at mid-exponential growth, resuspended in 50 mM HEPES buffer pH 8.0 and disrupted by French pressure cell treatment. Nitrogenase was purified under strictly anoxic conditions and separated into two components using a combination of DEAE-Sephacel chromatography in 50 mM Tris-HCl buffer pH 8.0 and gel filtration in 50 mM Tris-HCl buffer pH 8.0, 50 mM MgCl₂ essentially as described for nitrogenase from Klebsiella pneumoniae²⁶. Both proteins were then subjected to a linear NaCl gradient (0.25-0.4 M NaCl; total volume 300 ml) on DEAE-Sephacel equilibrated with 50 mM Tris-HCl pH 8.0 to remove contaminating proteins. Purified components were subjected to treatment with 1% SDS and 1% β -mercaptoethanol, electrophoresed as described previously²⁷ and stained wth Coomassie brilliant blue. Nitrogenase components (Ac1* and Ac2*) are compared with samples of conventional nitrogenase (Ac1 and Ac2) purified from A. chroococcum grown in Mo-sufficient conditions9.

components as Ac1* for the large protein and Ac2* for the small protein, where the asterisk distinguishes these proteins from the nitrogenase from Mo-sufficient cultures of the parent strain. Some physico chemical properties of the proteins are given in Table 1. Neither component contained significant amounts of Mo. V was present in stoichiometric amounts in Ac1* but not Ac2*. In the final purification step the highest levels of vanadium eluting from the column corresponded with the peak of activity for Ac1* (Fig. 3). Ac2* resembles a typical nitrogenase Feprotein. Ac1* resembles MoFe-proteins in subunit structure, although one of the two subunits is apparently smaller than that of Ac1 (Fig. 2). The presence of V in Ac1* is unlikely to be adventitious because it is present in stoichiometric amounts in purified protein of high specific activity (Table 1). This finding correlates with our observation that V is required for diazotrophy in MCD1155. Furthermore, our estimate of the specific activity for the vanadium stimulation of nitrogenase in whole cells (120 pmol H₂ evolved per min per pg atoms V) agrees closely with the activity per vanadium in the purified protein (160 pmol H₂ evolved per min per pg atoms V). Compared with H⁺ and N₂ as substrates, C₂H₂ is a poor substrate for the V nitrogenase (Table 1).

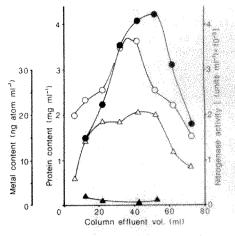

Fig. 3 Correlation of vanadium content of Ac1* with nitrogenase activity. The figure shows the elution profile of the larger component of nitrogenase (Ac1*, M_r 210,000) from DEAE-Sephacel under the conditions described in Fig. 2 legend. Nitrogenase activity (♠), Mo (♠) and V (△) and protein (○) contents of fractions across the peak are compared. Vanadium was estimated by atomic absorption spectroscopy on wet-ashed samples, while molybdenum was estimated colorimetrically²⁸. Quench corrections were made by the inclusion of internal standards for both metals. Nitrogenase activity was determined by complementation of fractions with Ac2* and assayed as ATP-dependent H₂ evolution as described elsewhere²⁶ (units of activity are nmol H₂ per min).

Reports that V can substitute for Mo for diazotrophy in azotobacters can be traced to Bortels¹³. Nicholas et al. 14 showed that nanomolar levels of V stimulated growth of A. chroococcum NCIMB 8003 in a Mo-deficient medium, which agrees with our findings for MCD1155. Becking15 showed that V replaced Mo in most strains of A. vinelandii and A. chroococcum tested. Biochemical studies on the vanadium effect led McKenna et al.16 and Burns et al.17 to prepare a crude V-nitrogenase from A. vinelandii and A. chroococcum which they proposed was the conventional nitrogenase in which Mo had been replaced by V. Some of the properties of their V-nitrogenase (for example, low electron allocation to acetylene) resemble ours. However, their preparations contained significant levels of residual Mo and their findings were attributed to a sparing effect of V on the amounts of Mo required for activity of conventional nitrogenase molvbdoprotein¹⁸. Our present findings confirm the reality of a V-nitrogenase but assign it to genetic determinants distinct from those of the Mo-nitrogenase which probably specify the alternative nitrogenase proposed by Bishop and his colleagues3-3, who suggested4 an involvement of V.

We propose in future to refer to conventional nitrogenase as Mo-nitrogenase and the alternative genetically distinct

Table 1 Comparison of physicochemical properties of components of Mo- and V-nitrogenase components of A. chroococcum

Marketine in the second of the		Metal content Subunit (g atoms mol ⁻¹)		Specific activities (nmol product per min per mg protein)			
	M_{r}	M_r	Мо	V	H ₂	NH_3	C_2H_4
Acl*	210,000	55,000 50,000	< 0.107	1.6	1,374	350	516
Acl	227,000	60,000	1.9	ND	2,138	1,521	1,924
Ac2*	60,000	31,500	0.012	0.04	1,107	507	999
Ac2	64,000	30,000	0.2	ND	1,993	1,361	1,830

For V-nitrogenase components (Ac1* and Ac2*), native and subunit relative molecular masses (M_r s) were determined by thin-layer gel filtration in Sephadex G-200 Superfine and SDS-electrophoresis as described elsewhere²⁶. Metal contents and activities were determined as described for Fig. 3. M_r and metal content of Ac1 and Ac2 are from ref. 9. Nitrogenase activity was measured as described in ref. 26, Ac1* (102 μ g) was complemented with Ac2* (1 mg); Ac2* (72 μ g) was complemented with Ac1 (0.14 mg). Ac1 (58 μ g) was complemented with Ac2 (0.32 mg); Ac2 (86.4 μ g) was complemented with Ac1 (0.29 mg). ND, not determined.

nitrogenase as V-nitrogenase, and the component proteins of the V-nitrogenase of Azotobacter chroococcum as Ac1* and Ac2* using the generally accepted nomenclature of Eady et al. 19. A. chroococcum contains two unlinked nifH genes encoding different Fe-proteins. The second copy $(nifH^*)$ that we have recently cloned and sequenced is likely to encode Ac2* (ref. 20). We have also shown that a nifK-like sequence, which might encode one of the Acl* subunits identified here, is present in the genome of MCD1155 (ref. 8).

Vanadium stimulates N2 fixation in Xanthobacter (Mycobacterium) flavus21 and Clostridium butyricum29. In Nostoc muscorum tungstate- or chromate-resistant mutants became dependent on these ions, respectively, but not molybdate, for N₂ fixation²², a situation which may parallel the apparent dependence of MCD1155 on tungstate. Thus, if azotobacters are not unique in this respect, vanadium may be a key element in the nitrogen cycle especially since it is more abundant in soils and fresh water than is molybdenum²³. Furthermore, it suggests that chemical systems based on vanadium which catalytically reduce N₂ (refs 24, 25) may have more biological significance than has hitherto been recognized.

We thank Simon Harrison for bulk growth of MCD1155, and Beryl Scutt and Brenda Hall for typing the manuscript.

Botulinum C2 toxin ADP-ribosylates actin

ADP-ribosylation of regulatory proteins is an important pathological mechanism by which various bacterial toxins affect eukaryotic cell functions. While diphtheria toxin catalyses the ADPribosylation of elongation factor 2, which results in inhibition of protein synthesis, cholera toxin and pertussis toxin ADP-ribosylate N_s and N_i, respectively, the GTP-binding regulatory components of the adenylate cyclase system, thereby modulating the bidirectional hormonal regulation of the adenylate cyclase^{1,2}. Botulinum C2 toxin is another toxin which has been reported to possess ADP-ribosyltransferase activity3. This extremely toxic agent is produced by certain strains of Clostridium botulinum4 and induces hypotension5, an increase in intestinal secretion6, vascular permeability and haemorrhaging in the lungs. In contrast to botulinum neurotoxins, the botulinum C2 toxin apparently lacks any neurotoxic effects5. Here we report that botulinum C2 toxin ADPribosylates a protein of relative molecular mass 43,000 (43K) in intact cells and in cell-free preparations. We present evidence that the 43K protein substrate is actin, which is apparently mono-ADPribosylated by the toxin. Botulinum C2 toxin also ADP-ribosylated purified liver G-actin, whereas liver F-actin was only poorly ADPribosylated and skeletal muscle actin was not ADP-ribosylated in

either its G form or its F form. ADP-ribosylation of liver G-actin by botulinum C2 toxin resulted in a drastic reduction in viscosity of actin polymerized in vitro.

Botulinum C2 toxin is a binary toxin and consists of two components, C2-I and C2-II, with relative molecular masses $(M_r s)$ of ~50K and 100K, respectively⁴. Both components are actually completely separate proteins which interact to cause the toxic effects. The 50K component, which is non-toxic in intact tissue, apparently represents the ADP-ribosyltransferase³. The 100K component appears to be involved in the binding of the toxin to intact cells⁶ and probably enables the enzymatically active component C2-I to enter the cell. Therefore, we used the combination of C2-I and -II for studies in intact cells and the isolated C2-I component for studies in cell-free preparations. In platelet lysates, C2-I toxin ADP-ribosylated a 43K protein, predominantly located in the cytosolic fraction (Fig. 1a). ADPribosylation of a 43K protein was also found in lysates of S49 lymphoma cells, hamster adipocytes, chicken embryo fibroblasts and neuroblastoma x glioma hybrid cells (NG 108-15) and in brain homogenates (not shown). As botulinum C2-I toxin ADPribosylated a protein with a M, similar to those of the N, and N_i proteins, the substrates of cholera and pertussis toxin, respectively, we studied the ADP-ribosylated substrates of all three toxins by SDS-gel electrophoresis. As shown in Fig. 1b, the 43K substrate of botulinum C2 toxin was clearly separated from the cholera toxin and pertussis toxin ADP-ribosylated regulatory components, N_s and N_i, respectively, of the adenylate cyclase system. When intact S49 lymphoma cells were pretreated with botulinum C2 toxin (components I and II), the subsequent C2-I-induced ADP-ribosylation of the 43K substrate protein in cell-free preparations was largely decreased (Fig. 2a). These findings suggest that the substrate of botulinum C2 toxin is identical in intact cells and in cell-free preparations. C2-Iinduced ADP-ribosylation of the 43K protein in platelet cytosol was time- and concentration-dependent. In the presence of 5 µM NAD, maximal ADP-ribosylation was seen at $\sim 1 \mu g \text{ ml}^{-1}$ toxin after 2 hours of incubation. That the ADP-ribosylation of the 43K protein was a mono-ADP-ribosylation under the conditions

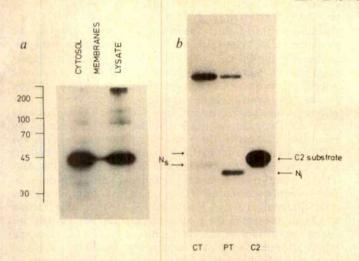

Fig. 1 Polyacrylamide gel analysis of radioactive products resulting from ADP-ribosylation catalysed by botulinum C2-I toxin, cholera toxin and pertussis toxin. a, ADP-ribosylation of a 43K protein in human platelet lysate, crude platelet membranes and platelet cytosol by botulinum C2-I toxin. b, ADP-ribosylation of the N_a and N_i proteins, and of the 43K C2 substrate in crude membranes of S49 lymphoma cells by cholera toxin (CT), pertussis toxin (PT) and botulinum C2-I toxin (C2), respectively.

Methods. a, Human platelets were isolated as described pre-viously11, then lysed by freezing and thawing in a hypotonic medium containing 10 mM triethanolamine-HCl (pH 7.4) and 5 mM EDTA. Platelet cytosol was obtained by centrifuging the lysate for 15 min at 30,000g. The pellet was washed twice with the hypotonic buffer then used as the crude platelet membrane fraction. ADP-ribosylation was carried out in a buffer containing 10 mM thymidine, 5 mM MgCl₂, 1 mM EDTA, 1 µg ml⁻¹ C2-I toxin, 0.5 μM [α-32P] NAD (~600,000 c.p.m.), 0.5 mM ATP and 50 mM triethanolamine-HCl (pH 7.4). Protein concentration was 50-200 µg per tube. After incubation of 37 °C for 1 h, the reaction was stopped by adding 1 ml of trichloroacetic acid (20% w/v). The resulting pellet was washed with ether and dissolved in 50 µl of electrophoresis buffer. SDS-gel electrophoresis was performed according to Laemmli12. Gels were stained with Coomassie blue, destained and subjected to autoradiography for 24-48 h. Thereafter, the protein bands containing the radioactive label were cut from destained gels, solubilized in the presence of 1 ml of 30% hydrogen peroxide and counted for 32P. ADP-ribosylation of the 43K protein in platelet lysate, crude membranes and cytosol was 24.7, 7.6 and 28.3 pmol ADP-ribose per mg protein per h, respectively. b, Crude S49 lymphoma cell membranes, prepared essentially as described elsewhere13, were incubated with 100 µg ml-1 cholera toxin, 40 µg ml⁻¹ pertussis toxin or 1 µg ml⁻¹ C2-I toxin for 45 min at 37 °C in medium containing 1 μM [α-32P]NAD (~1 µCi per tube), 10 mM thymidine, 10 mM arginine, 5 mM creatine phosphate, 0.1 mg ml⁻¹ creatine kinase, 5 mM MgCl₂, 1 mM EDTA, 0.5 mM ATP, 0.5 mM GTP and 50 mM triethanolamine-HCl (pH 7.4). Cholera toxin and pertussis toxin were preactivated by incubation in the presence of 20 mM dithiothreitol (DTT) for 10 min at 37 °C.

used is indicated by the following observations. First, whereas the total amount of the ADP-ribosylation increased with length of incubation, the M_r of the labelled substrate remained constant. Second, addition of snake venom phosphodiesterase hydrolysed the protein-bound radioactivity and resulted in the formation of 5'AMP (not shown).

The similarity between the relative molecular mass of the labelled protein and that of actin led us to study whether the platelet microfilament protein was ADP-ribosylated by botulinum C2-I toxin. After incubation with anti-actin antibodies but not with non-immune rabbit serum, protein A-agarose precipitated the toxin-labelled platelet cytosolic protein (Fig. 3a). In addition, immunoblotting with anti-actin antibodies clearly demonstrated that the antibodies recognized the labelled 43K protein (Fig. 3b). Both findings strongly indicated that actin

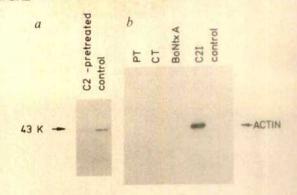

Fig. 2 a, Effect of pretreatment of intact S49 lymphoma cells with botulinum C2 toxin on the subsequent ADP-ribosylation of cell lysates. b, Effects of botulinum C2-I toxin, cholera toxin, pertussis toxin and botulinum neurotoxin A on the radiolabelling of liver Gractin

Methods. a, S49 lymphoma cells were treated for 24 h without (control) or with botulinum C2 toxin (5 μg l⁻¹ component I plus 10 μg l⁻¹ component II), then crude membranes were prepared and treated with botulinum C2-I toxin (1 μg ml⁻¹) in the presence of [α-3²P]NAD. SDS-gel electrophoresis and autoradiography were performed as described in Fig. 1 legend. b, Purified liver G-actin (100 μg ml⁻¹), prepared according to Jaberg¹⁴, was incubated without (control) or with 1 μg ml⁻¹ C2-I toxin (C21), 200 μg ml⁻¹ preactivated cholera toxin (CT), 30 μg ml⁻¹ preactivated pertussis toxin (PT) or 80 μg ml⁻¹ botulinum neurotoxin A (BoNtx A) in the presence of 0.5 μM [α-3²P]NAD (~500,000 c.p.m. per tube) as described in Fig. 1 legend.

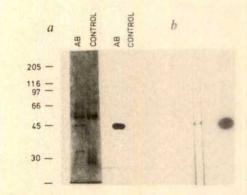

Fig. 3 Immunoprecipitation and immunoblotting of the platelet 43 K protein labelled by botulinum C2-I toxin. a, SDS-gel electrophoresis and autoradiography of the ADP-ribosylated C2-I toxin substrate immunoprecipitated by anti-actin antibodies (AB) but not by non-immune serum (Control). b, Immunoblot and autoradiography of the 43 K platelet cytosolic protein ADP-ribosylated by C2 toxin.

Methods. a, Platelet cytosol (~200 µg protein) was ADP-ribosylated as described in Fig. 1 legend, except that NAD and MgCl2 was at 1 µM and 0.5 mM, respectively and the total volume was 0.5 ml. Toxin-ADP-ribosylated platelet cytosol (200 µl), freed from unreacted [\alpha^{32}P]NAD by gel-filtration, was incubated in 1% Triton X-100, 1% deoxycholate, 0.1% SDS, 150 mM NaCl and 50 mM Tris-HCl (pH 7.2) with 100 µl of rabbit polyclonal antibodies (0.1 mg ml-1) for 12 h at 0 °C in a total volume of 400 µl. The antibodies were raised against heat- and SDS-denatured pig liver actin and affinity-purified over a column of rabbit skeletal muscle actin coupled to Sepharose 4B. Then, 20 µl of protein A-agarose (Sigma) was added for 1 h. The immuno-protein-A-agarose complex was separated by centrifugation, washed twice and analysed by SDS-gel electrophoresis. b, Anti-actin antibodies recognized the ADP-ribosylated toxin substrate. Immunoblotting was performed according to Towbin et al. 15 with peroxidase-coupled swine IgG to rabbit IgG (Dakopatts) as second antibody and 4-chloro-1naphthol as peroxidase substrate.

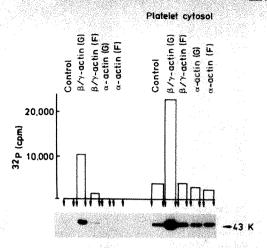

Fig. 4 Botulinum C2-I toxin-induced ADP-ribosylation of actin. For ADP-ribosylation purified liver G-actin (200 µg ml⁻¹) and F-actin (160 µg ml⁻¹) and rabbit muscle G-actin (200 µg ml⁻¹) and F-actin (110 µg ml⁻¹), prepared according to Pardee and Spudich¹⁶, were incubated without or with human platelet cytosol (170 µg ml⁻¹) in the presence of 1 µg ml⁻¹ botulinum C2-I toxin and 0.2 μM ³²P-NAD (~250,000 c.p.m. per tube) for 15 min at 37 °C. Reaction medium, SDS-gel electrophoresis, autoradiography and 32P measurements were as described in Fig. 1 legend.

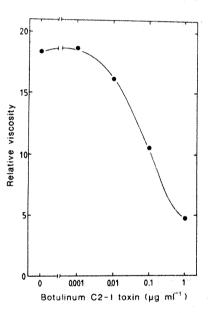

Fig. 5 Effect of C2 toxin-induced ADP-ribosylation on β/γ -actin polymerization, measured as relative viscosity.

Methods. Liver G-actin (30 µM) was incubated in the presence of 1 mM NAD, 10 mM thymidine, 0.5 mM MgCl₂, 0.5 µM ATP and 50 mM triethanolamine-HCl (pH 7.4) without or with botulinum C2-I toxin at the indicated concentrations for 1 h at 37 °C. Thereafter, the samples were placed on ice. Polymerization was initiated in 140 µl of the pretreated actin solution by adding 20 µl of a medium containing 16 mM MgCl₂, 1.6 mM ČaCl₂, 4.0 mM ATP, 0.8 mM DTT and 16 mM Tris-HCl, pH 7.5. Measurements were made after 10 min at 25 °C. Viscosity was determined using the falling-ball device described by Pollard and Cooper¹⁷. Relative viscosity is the quotient sample viscosity (η_s) divided by the buffer viscosity (η_a) .

was the protein ADP-ribosylated by botulinum C2 toxin. Furthermore, purified liver G-actin was a good substrate for botulinum C2-I toxin (Fig. 2b). In contrast, cholera toxin and pertussis toxin did not ADP-ribosylate the isolated microfilament protein. Botulinum neurotoxin A, which has no enterotoxic effects8, showed no ADP-ribosyltransferase activity with platelet lysates (not shown), brain homogenates (not shown), with purified liver G-actin. Interestingly, only the G-form of liver actin was a good substrate for the ADP-ribosylation by botulinum C2-I toxin. The F-form of liver actin was much less ADP-ribosylated, and purified α-actin from rabbit skeletal muscle was not ADP-ribosylated in its G- or F-form (Fig. 4)— Thus, it seems that botulinum C2 toxin-induced ADP-ribosylation is highly specific for β/γ -actin in its G-form. The slight ADP-ribosylation of liver F-actin may be due to a minor fraction of G-actin present in the F-actin preparation. Accordingly, we found that phalloidin, which specifically binds to F-actin and which stabilizes this form9, impaired or abolished the toxininduced ADP-ribosylation (data not shown). The addition of platelet cytosol to G-actin further increased the amount of ADP-ribosylation, suggesting that an additional factor present in the cytosolic fraction facilitated the ADP-ribosylation reaction. In contrast, the addition of platelet cytosol did not increase the ADP-ribosylation of liver F-actin or muscle α -actin.

In order to study whether the ADP-ribosylation of actin caused any change in the functional properties of the microfilament protein, we compared the viscosity of control and C2-I toxin-pretreated actin 10 min after induction of polymerization of actin with MgCl₂. When actin was pretreated with increasing concentrations of botulinum C2-I toxin, the relative viscosity of the polymerized actin solution was decreased in a concentration-dependent manner (Fig. 5). At 1 µg ml⁻¹ C2-I toxin, the relatve viscosity of ADP-ribosylated actin was reduced by about 72% compared with the control preparation, indicating that the polymerization of the modified actin was largely impaired.

Taken together, the data presented show that botulinum C2 toxin induces the ADP-ribosylation of β/γ -actin. This covalent modification subsequently alters at least one functional property of the microfilament protein, actin polymerization. It is suggested that the ADP-ribosylation of actin is the pathophysiological basis of the toxic effects of botulinum C2 toxin, for example, the increase in vascular permeability, gut secretion and haemorrhaging of the lungs. Recent findings that the C2 toxin induces rounding up and subsequent lysis of cultured cells, can also be interpreted in this sense 10. Botulinum C2 toxin, which clearly discriminates between non-muscle and skeletal muscle actin, appears to be an important tool for studying the physiological processes which involve non-muscle actin.

PLANKTONIC KIN RECOGNITION

Electrophoresis then and now

Then, in the early 70's, this was the latest thing in electrophoresis.

Now, it's the mid 80's, and there's a powerful new concept in high resolution electrophoresis.

PhastSystem

Run and stain SDS-PAGE gels in about 1 hour

PhastSystem combines precision equipment and new high-performance PhastGelTM media to give you:

- Fast results: from short separation times and quick protein staining. In total, SDS-PAGE and IEF each take about 1 hour. The resolution is superb.
- Quick staining: coomassie takes about 30 minutes, and silver staining about an hour.
- Reproducibility: you have automated, programmable control over running and staining conditions.

Try it for yourself!

GUIDE TO AUTHORS

Authors should be aware of the diversity of Nature's readership and should strive to be as widely under stood as possible.

Review articles should be accessible to the whole regidership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an italic heading of about 50 words.

Letters to Nature are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in Nature, The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London of Washington. Manuscripts should be typed (double spacing) on one side of the paper only. Four copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first

References should appear sequentially indicated by superscripts, in the text and should be abbreviated according to the World List of Scientific Periodicals, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be cited. Reference to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to uniless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Important: Manuscripts or proofs sent by air courses should be declared as "manuscripts" and "value \$5" for prevent the imposition of Customs duty and Value Added Tax in the United Kingdom.

Requests for permission to reproduce material from Nature should be accompanied by a self-addressed tand, in the case of the United Kingdom and United States, stamped) envelope

Catechism for nuclear power

Governments should urgently give attention to the consequences of Chernobyl on public opinion of nuclear power — and should correct some of the damage they have done.

High is a question from an examination paper in the final examination for students following the course in Logic for the Modern World, offered by the University of the Sticks, on which people may wish to brood.

 \mathbf{Q} . Even small doses of radiation exposure are potentially harmful to people, and should be avoided.

Nuclear power stations, and the nuclear industry in general, are sources of artificial radiation to which people may be exposed.

"Therefore nuclear power stations should not be built.

"Either explain in no more than 250 words which of the three statements in this syllogism is invalid or outline in no more than 50,000 words an alternative energy policy for your country of nationality, drawing attention to such social consequences as you can foresee."

Like most examination questions, this example begs a host of other questions, mostly unexamined. But the example is not nearly as hypothetical as it may seem. Especially in the aftermath of the Chernobyl accident, but not exclusively on that account, the imputed logic is increasingly coming to dominate the policies of governments across the world. And while there remains what may be called a hard core of people who believe that nuclear power remains an economic necessity, the syllogism cannot as easily as they would wish be demolished in the prescribed 250 words.

Radiation

Those familiar with exercises like these will nevertheless quickly know the truth, that the insidious errors are in the premise. Once that has been swallowed, the conclusion tends to follow as night follows day. Nuclear power stations and the nuclear industry in general are, indeed, sources of radiation to which people, either workers in the nuclear industry or the general population. may be exposed. The British population, and British farmers in particular, have recently been given a dramatic proof of that by the decision of the agriculture ministry to ban the sale of fat lambs on the flimsy grounds that some were found to contain just over 10 per cent of the amount of Chernobyl caesium that would have been permitted by the emergency reference levels promulgated earlier this year by the British National Radiological Protection Board (see Nature 321, 798; 1986). Earlier, the whole European Community had been reminded that power stations are potentially powerful sources of radiation by the decision, at Brussels, that imports of foodstuffs from Eastern Europe would be prohibited while the content of radioactivity exceeded 600 Bu per kg. 6 per cent of the same reference level. The effect of these and other decisions has been to dramatize the truth that nuclear power stations are potential sources of radioactivity, which may be geographically widespread. The lesson will now be firmly embedded in the public consciousness, as it should be. So, given the premise, the conclusion follows that nuclear power stations are an abomination and should not be built.

As it happens, the bulk of the premise is also correct. "Even small doses of radiation exposure" are indeed potentially harmful to people. The days have long since gone when it was permissible for politicians and others to canvass the idea that there is a

"threshold" dose below which no damage of any kind is done to living organisms. While much remains to be learned about the biological consequences of small doses of radiation, the best assumption is that the probability of a particular kind of damage is proportional to the radiation dose, however small. To be sure, it is possible that in the causation of some kinds of cancer by radiation (or even other agents), where two separate damaging interactions between radiation and tissues may be required to trigger the neoplastic process, the risk of damage may be proportional to the square of the dose. But, in the present state of ignorance, nobody would go to the stake for that hypothesis. which would in any case only partially restore the respectability of the notion that there are thresholds below which no damage of this particular kind — carcinogenesis — is done. And where genetic damage is in question, there seems (at least for the time being) no sensible alternative to the proposition that the risk of damage is proportional to the dose.

Risk

The circumstance that different kinds of radiation exposure are potentially damaging in different ways does not undermine the validity of the first part of the premise in the examination question, although this circumstance enormously complicates both the estimation of risk and the general understanding of why radiation is hazardous. It is now a familiar circumstance that different sources of radiation, natural or artificial, must be dealt with differently in the estimation of biological effects. Naturally occurring radon (on account of its decay products) and airborne radioactivity are potentially causes of lung cancer to the extent that they are trapped in the airways of the lungs. Naturally occurring potassium-40 and artifical caesium (as in British post-Chernobyl lambs) once ingested, expose the internal organs of the body almost equally to potentially damaging doses of radis ation. Both plutonium-239 and strontium-90 concentrate in bones and are a threat to bone marrow, but, becquerel for becquerel, plutonium-239 is more damaging than strontium because alpha particles deposit their energy along shorter paths of ionization. And so on. There is far too little public understanding of the sophistication now applied by the radiological protection people as a matter of routine to the unravelling of the once-daunting complexity. Yet none of this qualifies the general principle that the potential hazard of a radiation dose (of a particular kind) is probably proportional to its amount.

The catch in the premise is the hanging qualifier in the premise, the seemingly innocent phrase "and should be avoided". This, of course, is not so much the starting point for a syllogism but the conclusion of some other. Moreover, whether premise or conclusion, it cannot be taken by reasonable people as an absolute injunction against radiation exposure. If it were such, the whole pattern of civilized life would already, during the half-century in which understanding of the hazards of radiation have accumulated, have been transformed. People would no longer live, or be allowed to live, at high altitudes or even high latitudes, on account of the extra doses of cosmic radiation to which they are there exposed. Old granite shield areas, where radon in the atmosphere accounts for up to a third of natural exposure.

would be evacuated. Jet aircraft would be disallowed. And so on

The truth, of course, is that the principle that radiation exposure is best avoided is not now, and never can be, absolute. Merely to rationalize present patterns of life, people have to acknowledge that the heavily loaded part of the premise must be extended somehow, perhaps to read "should be avoided whenever possible" or, more tangibly, "should be weighed in a costbenefit calculation and then, when the costs exceed the benefits, avoided". The snag for the simplifiers is that any such qualification undermines the logic of the syllogism. Only if the interdiction of radiation exposure is absolute does the conclusion follow that nuclear power stations must never be built. In all other circumstances, the most that can be said is that the benefits of nuclear power must be weighed against the costs, one of which is the potential damage done by radiation exposure, both as a matter of routine (to workers at reprocessing plants) and after accidents (as at Chernobyl).

All this is familiar stuff. For thirty years, those who build (or would build) nuclear power stations have been saying just this. It may be true that, for much of that period, the professionals have been less than frank about the potential scale of the hazards, but nobody has sought to conceal the need for a rational trade-off between risks and benefits. What Chernobyl might rationally have accomplished is a demonstration that, within a well-run nuclear programme, the avoidance of major reactor accidents deserves even more attention than it has received since the close attention given to the problem by the monumental Rasmussen study just over a decade ago. It is also possible to argue that it is worth paying something extra to avoid self-imposed risks, such as those unavoidably attending a nuclear industry, on the principle that there is a difference between unavoidable sources of risk (cosmic rays, for example) and those that are self-imposed. Yet even that seductive argument leaks. By what tests is it virtuous to claim (as the British Labour Party now does) that nuclear power should be replaced by coal when one of the few certainties in the trade-off is that many more miners will be killed per gigawatt-hour in the coalmining industry than members of the public by exposure to the radiation accompanying the routing operation of a nuclear industry?

If Chernobyl and its consequences were to lead to a more public re-examination of these questions in the countries where nuclear power is potentially an economic benefit, nobody would complain. The trouble is that the accident has come at a time when the populations most likely to need nuclear power in the decades ahead have been dissuaded from regarding the issues calmly by siren voices seeming to proclaim that there is such a thing as a free lunch — electricity without the risk to those who consume it. The sad truth is that governments are often unwittingly the abetters of these seductive propagandists, as when European governments band together to settle on a limit for the contamination of imported foodstuffs that provocatively plays over-safe. They seem not to have appreciated that, by taking such a line, they have gone a long way to accepting the loaded premise of the false syllogism which will be used against them when they plan to build a nuclear reactor. Is it too late to ask that they should mend their ways?

Teaching by numbers

A British committee has produced an enlightening report on future trends in education.

What is the difference between a teacher and a teaching machine? This question, widely asked in the sense pejorative of teachers a decade or more ago, has usually been answered by the claim (usually on behalf of teachers) that even the best teaching machines are merely mechanical, incapable of firing the imagination and the aspirations of students. For the most part, the teachers' case has been vindicated by the appalling quality of

what has previously been passed off under the label of educational technology. Some teaching machines have been literally machines whose mastery required not merely skills available to, say, high-school students, but those of ambidextrous conjurors as well. Others have looked like books but have been seen, on casual inspection, to be ways of drilling students in lessons which it is possible, but inappropriate, to learn by rote, leaving the real work to be done by real teachers. It is no wonder, that after a brief fashion for educational technology in the 1960s, the exercise should have been discredited. But equally, now that professional people are agog with the idea that "expert" systems should be used as aids to judgement in fields as different as medicine and engineering, it is natural that the old claims of educational technology should be dusted off and re-examined.

One result, in Britain, is a sensible slim document by a government committee called the Information Technology Advisory Panel, set up when Mr Kenneth Baker, now Secretary of State for Education and Science, was the British government's cheer leader for the information revolution. One irony is that most of the panel's recommendations urge that the government should spend money on investigation and research on the application of information technology; Mr Baker, in his new role, would have to foot the bill. Another is that the panel was subsumed last April in another government committee, the Advisory Committee on Applied Research and Development, whose most recent public report some weeks ago consisted of an extended wringing of hands over the parlous condition of the British software industry, from which many of the defunct panel's members spring. Yet, curiously, the panel's report (Learning to live with IT, HMSO £4.00) is just the judicious blend of enthusiasm for change and caution about the means by which it may be accomplished that endears a committee to its discriminating followers.

On the leading question, not directly answered by the panel, the difference between a teacher and a machine is that the teacher alone can serve as an intelligent critic of an individual student's learning. Machines, of course, can automatically assess a student's performance by criteria written in their programs, providing reinforcement exercises whenever these seem necessary. But even as machines are now, or are likely to be tomorrow, there is only a poor prospect that they will be able to handle the unexpected difficulties that arise in most people's learning, among which the recurring question "Why bother?" is the most frequent. In one of its rosier passages, the panel does venture the guess that the simulation of the teacher's skills by sufficiently expert systems is not impossible, but for the most part it recognizes that the immediate need is for experiment and investigation to define the bounds of what may be possible.

The belief that the time has come for another wave of interest in new educational technology is even stronger than the panel says. First, and most notoriously, this is a time when few technically advanced societies are able to recruit enough skilled teachers for what are considered essential tasks, teaching mathematics or science more widely, for example. Shortages are especially acute in the field with which the panel is chiefly concerned, information technology. Second, because of the rapidly changing ethos of the high school, students are no longer content to sit and watch teachers make marks with chalk on the walls of the rooms they inhabit but appear (to teachers) to be subversively bent on deciding for themselves what they wish to learn, which is often a recipe for learning (too late, as things are) from their mistakes. Third, there is much more to learn, in circumstances in which the educationalists have not so far been able to devise a curriculum for the modern teenager. Fourth, this is a time when the old advocacy of the cause of continuing education has become an economic necessity; one package of youthful skills no longer lasts a lifetime. How, in these circumstances, can anybody resist this modest committee's appeal for a modest subvention of a programme to find out what computers have to offer students? Not, surely, Mr Kenneth Baker?

British radioactivity

Sellafield remains at the centre of the storm

LIVING with radiation in Britain has come to require the intellectual stamina for digesting a plethora of technical and often conflicting documents. This is the experience of the past few weeks, which have seen the publication of the first report from the newly appointed Committee on Medical Aspects of Radiation in the Environment (COMARE); the government's response to a critical report on waste management from the House of Commons Select Committee on the Environment; and a further slew of documents from the National Radiological Protection Board (NRPB).

COMARE, which owes its existence to a recommendation of the report two years

Paying for old lambs

Confusion persists in Britain about arrangements for compensating farmers for the consequences of the ban on the sales of lamb after the accident at the Soviet nuclear power station at Chernobyl. Farmers affected, in North Wales and Cumbria, have been told that the British agriculture ministry will pay compensation to farmers able to show they have suffered loss by having to keep lambs off the market for so long that they no longer qualify for the premium prices paid for lean animals.

But suggestions that the British government will pass the bill, which might amount to £10 million, onto the Soviet government, are premature. That, a spokesman at the agriculture ministry said last week, would be a matter for the Foreign and Commonwealth Office.

Restrictions of the sale of lambs through agricultural markets are being progressively removed, and now apply only to the Lake District region of Cumbria. They were introduced at the beginning of last month because the caesium-134 content of lambs from the affected regions exceeded 1,000 Bq per kg, a limit adopted by the ministry as an "action level" after an ad hoc meeting of a European Community advisory committee. The Emergency Reference Level recommended by the National Radiological Protection Board (NRPB) earlier this year is ten times as much, or 10,000 Bq per kg.

As yet, it seems, no British farmer has made a formal application for compensation. There appears to be no plan to compensate farmers for reduced prices from the sales of lamb from farms outside the two affected areas.

ago by Sir Douglas Black about the occurrence of excess leukaemia deaths around the Sellafield reprocessing plant, ironically begins its life by correcting in its *First Report* (HMSO, £4.40) the Black report's calculations.

The unexpectedly high incidence of leukaemia in the neighbourhood of the reprocessing plant, first publicized by a television company, is now accepted as a valid observation which was, in fact, the stimulus for Sir Douglas Black's inquiry. The conclusion of that report was that leukaemia incidence in the neighbourhood of the plant, especially among people born in the 1950s, was indeed greatly in excess of the expected average incidence but not necessarily inconsistent with random fluctuations within the small population concerned.

The committee is however exercised by the discovery that the Black inquiry, which was provided with an official history of radioactive discharges from the Sellafield plant, including that from the fire in the core of a plutonium-producing reactor in 1957, was not told of an incident in which fission products from spent uranium fuel elements had been released to the environment in 1954 and 1955.

The circumstances are odd, and have come to light because of representations by Dr Derek Jakeman, now a reactor physicist at the Winfrith Heath Research Establishment of the UK Atomic Energy Authority (UKAEA), but an employee at the Sellafield (then called Windscale) establishment in the 1950s. Jakeman was one of two employees who called attention to the unsuspected release of radioactivity from the two plutonium reactors on the basis of measurements of soil from his garden near the plant.

Jakeman said this week that irradiated uranium metal fuel elements occasionally incorrectly discharged from the plutonium reactors in 1954 and 1955 would lodge inaccessibly behind a concrete shield and would be allowed to oxidize in the ambient air. He estimated at the time that several kilograms of uranium and associated fission products would have been discharged in oxide form to the local environment. His revised estimate is that a total of 30 kg of uranium and its associated fission products would have been released over a period of perhaps two years; a formal report on Jakeman's reconstruction of this leakage will be published by the Winfrith establishment in the next few days.

What concerns COMARE is that infor-

mation about this release was not provided to the Black inquiry, and that a search of UKAEA archives since carried out did not uncover a reference to the incident. The committee says that the "way in which these data came to light is unsatisfactory and undermines our confidence in the adequacy and the completeness of the available data". The committee nevertheless accepts that the increased radiation doses to young people living nearby in the 1950s are at once less than the natural background and insufficient to account for the leukaemia incidence.

The recalculation of the exposure of the Sellafield population to artificial radioactivity has been carried out by NRPB (NRPB-R171-Addendum) in the light of the further information about the uncontrolled oxidation of fuel elements in 1954-55, information about other recorded discharges report to the Black inquiry and new assumptions about the rate of absorption of plutonium and americium in the gut which have recently been recommended by the International Commission on Radiological Protection (ICRP). The effect is to increase the expected incidence of leukaemia as a consequence of discharges from the Sellafield plant by roughly two-thirds, giving an expected number of cases of 0.16 among the study population of 1,255, which is statistically much less than the 4 cases on which controversy continues to centre. NRPB's recalculation also distinguishes between the effects on bone marrow of radiation with high and low linear-energy transfer (LET) in tissues; its report says that although the biological effects of high-LET radiation may have been underestimated, supposing that the degree of underestimation would suffice to explain the four known cases of leukaemia would require that the incidence of leukaemia on account of natural radiation would be much greater than is observed away from nuclear plants.

Sellafield is also the chief focus of the British government's reply to the House of Commons select committee's report, which argued on 12 March that the new reprocessing plant being built at Sellafield to handle oxide fuel from pressurized water reactors should be abandoned. The government now says (Radioactive Waste, Cmnd 9852, £3.40) that the financial consequences of abandonment would involve the waste of £600 million already spent on the plant.

More significantly, the government's response also holds robustly to the view that extracting fissile material from spent uranium fuel is a necessary preparation for the next century "when nuclear power will have an essential contribution to make". In other respects, as in its willingness to specify limits for the discharge of gaseous radioactivity to the atmosphere, the government is conciliatory.

Genetic engineering

Hepatitis vaccine wins approval

Washington

THE US Food and Drug Administration last week approved for the first time the sale of a human vaccine made by recombinant DNA techniques. The vaccine, for hepatitis B, is to be manufactured by Merck, Sharp and Dohme of West Point, Pennsylvania, under the name Recombivax HB, and was developed in collaboration with Chiron Corporation of Emeryville, California.

Recombivax has a potential world market of hundreds of millions of doses for, unlike existing hepatitis-B vaccines, production is not limited by the need for plasma from infected patients. But at \$100 for the course of three injections, the vaccine costs about the same as conventional plasma-derived vaccines and is far too expensive for mass immunization programmes in countries where the disease is most common.

In East Asia and tropical Africa, more than 10 per cent of the population are chronic carriers, and active hepatitis and related cirrhosis are major causes of mortality. Worldwide there are about 300,000 liver cancer deaths per year, most of them thought to result from hepatitis-B infection. In the United States there are 200,000 new cases of hepatitis each year. Those most at risk are offspring of infected mothers, health-care workers, intravenous drug users and male homosexuals.

Although a plasma-derived vaccine, also sold by Merck, has been available in the United States since 1981 only 3 - 30per cent of high risk groups have been vaccinated, partly because of fears that the vaccine might transmit acquired immune deficiency syndrome (AIDS). Although Merck says these fears are groundless the company hopes that the recombinant vaccine, which is produced in yeast cells, will prove more acceptable to members of high-risk groups.

Recombivax is made intracellularly in yeast cells that express the hepatitis-B surface antigen. Since early successes were reported in Nature (298, 347; 1982), a more complex expression system has been developed, and improvements in expression and scale-up work done by Merck. Patents governing the process are held by the University of California, by Chiron and by the University of Washington. But there is a continuing dispute over some patent rights to the viral genome with Pierre Tiollais' group at Institut Pasteur in Paris, which was the first to obtain a complete viral sequence. The US Patent Office is likely to declare an "interference procedure" to consider the French claims. In the short term, the factor that will limit use of the recombinant product is price. Dr Joseph Melnick of Baylor Col-

lege of Medicine estimates that the price of a treatment would have to come down to around \$1 to be widely used in mass immunization campaigns in the poorest countries, but is optimistic that the potentially unlimited supply of new vaccine will lead to its widespread use.

Dr William McAleer of Merck is also optimistic, believing that the recombinant vaccine made in yeast will in the long term become cheaper than the existing plasmaderived product. McAleer argues that constructing a suitable high-yielding clone has been the most expensive part of development; extraction and purification procedures are inherently cheaper for yeast-derived than for plasma-derived vaccines, because inactivation steps and innocuity testing are less elaborate.

The hepatitis-B antigen particles in

Recombivax are not identical to those from infected humans because they do not include polypeptides coded by the "pre-S' regions of the viral coat gene. In addition, lipid membrane in the particles is from yeast rather than human cells. Nevertheless, about 95 per cent of volunteers immunized in trials developed a strong antibody response and are presumed to be protected. But Chiron has already produced an experimental vaccine that does include pre-S polypeptides, and it is hoped that it will provoke immunity in those who do not respond to the Recombivax HB.

Recombivax is Chiron's first therapeutic product to gain marketing approval and the company expects it to earn at least \$100 million a year. The only competitor is sold in Singapore by Smith Kline-RIT, a subsidiary of SmithKline Beckman based in Belgium. But Institut Pasteur in Paris and Genentech in the United States are likely to enter the market and then prices may fall. **Tim Beardsley**

UK research grants

Research board pleads for more

EACH year seems to deepen the despair of Britain's Advisory Board for the Research Councils (ABRC). In its annual claim for research funds, now under consideration by the Secretary of State for Education and Science, it finds need to reiterate, in bold type, that scientific research is relevant to "national needs". A series of increases in science spending over the next three years is called for.

The argument the report seems repeatedly to try to drive into the minister's mind is that the new technologies, principally

biotechnology and information technology, that the government hopes will revitalize the economy, are science-based and crucially dependent on advances in basic research. Demands on the science base, particularly from industry, are thus increasing while the volume of scientific research performed is falling because funds are not available. Evidence of the failure to keep up with other countries in investment can be seen in the brain drain

an describer de la companya de la c

of scientists from the United Kingdom and in a study from the Science Policy Research Unit that shows the per capita expenditure on science in to be the lowest in the industrialized world.

The report protests that everything that can be done to make better use of available money has been done. Dozens of research units have been closed, and more than 3,000 jobs lost to try to give better value for money.

But very little scope remains. If, as the report speculates, it is the government's intention to have a much smaller science base in Britain, there is not even enough money for an orderly transition.

By 1990, the volume of research supported will be some 10 per cent less than at the beginning of the 1980s, despite the value of the science budget having been maintained. The trouble is that the costs of scientific equipment and materials rise much more rapidly than does inflation and this needs to be reflected in the budget.

To end the erosion of research the board asks for an increase over present figures (some £614 million in 1986-87) of £35 million in 1987-88, £50 million in 1988-89 and £60 million in 1989-90. In addition, the Science and Engineering Research Council needs an immediate £9 million to compensate for recent rises in the cost of its subscriptions to international laboratories.

The signs are that the government will be hard to persuade. A white paper (policy document) released last week rejected recommendations from a select committee that the science budget be increased annually by at least three per cent above inflation. **Alun Anderson**

Human genome

No consensus on sequence

Washington

"Can it be done? Yes. Will it be done? Yes." With those words, Donald Fredrickson, president of the Howard Hughes Medical Institute, introduced a conference sponsored by his institute on the sequencing of the human genome. But as Fredrickson quickly acknowledged, the questions of how it should be done, when, by whom and who should pay are still up in the air.

What emerged from the conference was a consensus that a physical map of the genome, consisting of an ordered set of cosmids, should be constructed as soon as possible. There is also considerable support for a restriction fragment length polymorphism (RFLP) map.

But few are as enthusiastic when it comes to contemplating the task of sequencing the estimated 3,500 million base pairs in the human genome. "I'm in favor of it", says Cold Spring Harbor director James Watson, "and everyone else at Cold Spring Harbor is against it." The reason is money. Watson thinks there is wide support for starting initial mapping, but many feel that a commitment to determining the sequence will draw resources from other activities.

John Tooze, executive secretary of the European Molecular Biology Organization (EMBO), agrees it would be a disaster if current projects had to compete for funds with the sequencing project. Tooze believes European governments would be hard-pressed to find additional funds, making competition inevitable.

Leroy Hood of California Institute of Technology says it would be a "serious mistake" to jump into a full-scale sequencing project now, as automation will speed sequencing by one or more orders of magnitude in the next few years. Ironically, one of the factors that sparked interest in the sequencing project was the imminent commercial appearance of the automated DNA sequencer that Hood helped to develop (see *Nature* 321, 674; 1986).

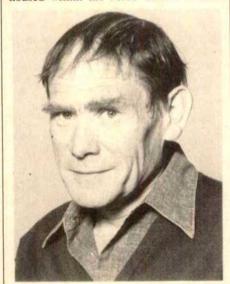

A sequence for the entire human genome, while itself a goal, is only a tool for a better understanding of human genetics, points out Eric Lander of the Whitehead Institute in Cambridge, Massachusetts. Just knowing the sequence tells you almost nothing, argues Lander; it will be useful only when coupled with a better understanding of the structure and function of proteins. Toward that end, Tooze says the European Molecular Biology Laboratory will be putting more of its resources into biocomputing and crystallography.

There has been no dearth of meetings to discuss the sequencing project this year,

and there are more to come. In February, the Howard Hughes Medical Institute conducted a preliminary meeting on the topic in Florida. In March, the Department of Energy hosted a meeting in Santa Fe, New Mexico, and in June the topic was the focus of a Cold Spring Harbor symposium (see *Nature 322*, 11; 1986). Next month, the National Academy of Sciences will air its views at a meeting in Woods Hole, Massachusetts, and in October the National Institutes of Health will discuss what their role in the project ought to be.

New career for Sydney Brenner

DR Sydney Brenner, director of the Medical Research Council (MRC) Laboratory of Molecular Biology in Cambridge, is soon to have a chance to give up administration and pursue his own personal research. This week, MRC announced that it has set up a new Molecular Genetics Unit which Brenner will head from 1 October this year until his retirement. The unit will be a small one, of 4 or 5 researchers, housed within the MRC Centre in Hills

Sydney Brenner

Road, Cambridge. Four hundred thousand pounds will be provided to establish the unit and a budget of £200,000 a year awarded thereafter. Research at the unit will concentrate on areas in which Brenner has already won international renown: methods of gene mapping; the characterization of genes affecting the development of the nervous system in Caenorhabditis elegans; and aspects of gene evolution. Dr Aaron Klug, who won the Nobel prize for Chemistry in 1982, will succeed Dr Brenner as director of the Laboratory of Molecular Biology.

Alun Anderson

Enthusiasm for starting the sequencing project continues to run high at the Department of Energy. The department has already started constructing a physical map of the human genome, as well as supporting research on database management and automated data entry. But its cost estimates for the sequencing project have dropped considerably during the past year — down by an order of magnitude from the \$3,000 million that was thought necessary at the March meeting.

In spite of uncertainty about how best to proceed with the project, Sydney Brenner, director of the Medical Research Council Laboratory of Molecular Biology in Cambridge, United Kingdom says that everyone interested in medical research ought to be interested in the sequence of the human genome. Those that are not, says Brenner, "have to be considered a subject for appropriate treatment".

Joseph Palca

David Swinbanks in Tokyo adds: It would take US \$600 million and 30 years to sequence the entire human genome by a "sequencing factory" according to Akiyoshi Wada, professor of biophysics at Tokyo University. While that may seem a lot, he estimates that if it was done by 100 experts it would take \$1,100 million — and 250 years.

Since 1981, Wada's group has been trying to develop an automated DNA sequencing system in collaboration with industry under the support of the Science and Technology Agency. A robot that performs DNA fragment separation according to the Maxam-Gilbert or Sanger M13 protocol (see Nature 307, 193; 1984) has been developed with Seiko Instruments and Electronics Co. And Toyo Soda Manufacturing Co. has designed a specific DNA extractor with high base resolution, while Fuji Photo Film Co. has created a system for mass production of films for gel electrophoresis.

Now Seiko and Hitachi Software Engineering Co. are competing in development of machines to read the gels and type out the sequence. By combining these operations, Wada estimates that it should be possible to sequence one million base pairs per day.

Once a working system is developed, Wada thinks that sequencing should be extended to all parts of the genome, not just those of immediate interest. He compares the operation with geographic mapping, which is carried out irrespective of the "profitability" of the area to be mapped.

If a sequencing factory can be built, Wada emphasizes that it would not be "Japan Incorporated" against the rest of the world. He wants an international centre that would be open to scientists of all nationalities and intended for the benefit of all mankind.

Biotechnology

Regulations please nobody

Washington

CONTROVERSY continues in the United States over the federal government's proposals to regulate biotechnology. At a recent congressional hearing, representatives of the American Society for Microbiology, the Environmental Law Institute and the Ecological Society of America all criticized the administration's plan to exempt from high-level review environmental releases of intergeneric organisms whose introduced genetic material is "well-characterized and contains only non-coding regulatory regions".

The administration's latest proposals on biotechnology regulation were published after much delay on 26 June. They recognize that non-living products of genetic engineering technology should be regulated in the same way as conventionally made products, but require that environmental releases of engineered organisms containing DNA from different genera or from a known pathogen should receive high-level review. The exemption for transferred non-coding regulatory sequences applies whether or not the donor organism is a known pathogen.

The proposals were examined last week at a joint hearing by three subcommittees of the House of Respresentatives' Science and Technology Committee. Monica Riley, chairman of the American Society for Microbiology, said that "strain construction that places a strong, effective regulatory sequence in a position of control over any particular gene can increase the expression of that gene many fold", thus affecting a microorganism's capacity to compete. Riley also pointed out that regulatory sequences carry specific determinants that turn genes on or off; changing the signals to which a gene responds could constitute a substantial change in the biology of the recombinant organism.

Some congressional staff speculate that this criticism from respected professional bodies might persuade the administration, which is anxious not to overburden the emerging biotechnology industry, to remove the exemption. Industry organizations publicly support the administration's proposals, but some privately concede that the non-coding exemption could undermine public support and they would rather have it removed.

Meanwhile, the administration's plan has come under attack from a more predictable quarter. Jeremy Rifkin of the Foundation on Economic Trends has sued the government for omitting to conduct an environmental impact statement and failing to keep an adequate record of its development.

Tim Beardsley

West German nuclear power

The fast breeder is stumbling

Hamburg

REIMUT Jochimsen, Social Democratic Economy Minister of Nordrhein-Westfalen, has put aside political questions and called for a halt to the fast-breeder programme on scientific grounds. Fulfilling his earlier promise to keep scientific and political issues separate, he has published an expert opinion (roughly 100 pages long) written by co-workers in his ministry, where grave doubts are raised about the safety of the 300 MW prototype reactor. The problems are enough, Jochimsen emphasizes, to make the fast breeder the most expensive misinvestment ever in industrial history.

The report clearly shows that politicians have been careless in trusting the calculations of engineers from the reactor building and operating companies, in particular those of the Schnellbrüter-kraftwerksgesellschaft (SBK), on which many of the 17 permits already granted were based. Under certain very adverse conditions, a runaway reaction could take place. In contradiction to earlier claims, there are serious doubts about the breeder's safety.

In 1984, experts of the companies involved said in court that a disastrous failure of the ventilation system was impossible. This expert opinion proved wrong when after less than two years of routine test running (without nuclear fuel cells) two of the ventilation devices failed. The experts also excluded absolutely the possibility that oil could enter the radioactive primary system of the reactor. But that happened. Never, they said, could water and sodium, the reactors' primary coolant, meet. But that too has happened.

Parts of the reactor, which must never fail, are called "holy" by the technicians. But some of them have been found to be not safe under any conditions. A grating to hold the fuel cells, for example, can rust. Jochimsen said that for such parts a "repeatable control" is necessary, which is impossible in the planned prototype. Rust has also (as long ago as 1980) been found in the reactor tank, and technicians have found weaknesses in weld seams. The method of estimating the probability of a runaway accident was not scientific, the report says. All the Gesellschaft für Reaktorsicherheit (the company responsible for reactor safety) did was to ask selected experts if they though such an accident likely. Another analysis, carried out at the Kernforschungszentrum Karlsruhe, was found to be incorrect due to a faulty computer program.

Opponents of the Jochimsen report, such as the leader of the Nordrhein-Westfalen Christian Democrats, Kurt Biedenkopf, say that its arguments are

false. The truth, they say, is that Jochimsen is executing the Social Democratic Party's decision to stop the nuclear programme. A representative of the Ministry of Research and Technology said that Jochimsen's political intentions are evident because the minister published his paper only 11 days after the Nordrhein–Westfalen members of the Social Democrats had decided to stop the breeder. This accusation is hard to believe, however, for the report cannot have been produced so quickly.

Critics have not attacked the technical arguments presented, Jochimsen points out, but only produced political arguments. The head of SBK, August Wilhelm Eitz, argues that all necessary modifications will be made. But that still leaves one key objection from Jochimsen: in the foreseeable future, there is no acceptable place and method for disposing of the nuclear waste from the reactor.

The Social Democrats now want to go further. In Nordrhein-Westfalen, permission will not be given for new sites for nuclear plants. The party is working on a bill to be introduced into the Bundestag in the autumn. According to representatives, it demands that no nuclear plants at all should be permitted to run in West Germany, even those already built. Preferential treatment for nuclear energy should be ended. In addition, the Social Democrats will introduce clear standards of radiation analysis and protection to avoid the confusion experienced after the Chernobyl disaster. The law, which could come into force if the Social Democrats win next year's federal elections. would also automatically terminate the DM7,000 million breeder. The Nordrhein-Westfalen government cannot enforce a decision on its own because the federal government can make it grant permission for the fast breeder reactor.

Heinz Riesenhuber (CDU), Minister of Research and Technology, has already mentioned that option in an interview, but he knows that it is unlikely to be successful. On the other hand, if he abandoned the project he could save more than DM200 million. The problem is very delicate and the legal situation unclear. If the project is stopped without definite technical reasons, the power supplier will get back the DM1,400 million it paid. Belgium and the Netherlands will also want their DM1,600 million returned. If, however, Jochimsen's paper is telling the truth, the reimbursement need not exceed the present value of the plant, which would not be very high, given a plant too dangerous to run. A meeting planned for September should make things clear.

Jürgen Neffe

Atomic power

No nuclear doubts for Japan

Tokvo

By 2030, Japan will have more than 120 nuclear power reactors supplying over half the country's electricity needs. Fastbreeder reactors will be on line, and fuel evele facilities will provide a large proportion of the nuclear industry's enriched uranium requirements, reprocess most of its spent fuel and store all its waste. Such is the "vision" of Japan's nuclear industry outlined in a report recently submitted to the Ministry of International Trade and Industry by the nuclear subcommittee of the Advisory Committee of Energy. But where will all these nuclear plants be located and will the Japanese public willingly accept them?

Japan has 32 reactors generating nearly 25 million kilowatts, putting Japan behind the United States, the Soviet Union and France in total nuclear capacity. Twenty-six per cent of Japan's electricity is nuclear generated.

According to the report, nuclear power capacity will more than double to 62 million kilowatts by the end of this century and, assuming a growth in Gross National Product of 2.5 per cent, rise to 137 million kilowatts by 2030 to provide 58 per cent of Japan's needs. This will require the construction of 116 new reactors at the rate of 2 or 3 a year. Ten new reactors are under construction and seven more are planned.

Two areas in Fukui and Fukushima prefectures contain most of the nation's nuclear plants. Their presence has brought economic benefits but there is resistance to further expansion. The town of Ohi in Fukui Prefecture, for example, has earned more than Y11,000 (£47 million) in fixed property revenue funds, grants from the central and local government and redemption taxes during the past 15 years. But plans to double the number of reactors in the town to four have led to mass demonstrations; in 1984 1,400 riot police had to be mobilized to contain thousands of demonstrators protesting outside public hearings in the town.

The subcommittee's report makes several recommendations to promote public understanding of nuclear power so that expansion can proceed "smoothly". Safety should be strictly maintained in the plants to ensure the public's understanding of the "safety" of nuclear power. Nuclear power technology should be explained in simple, easy-to-understand terms, and the central and local government should positively promote nuclear power in school education.

Japan certainly has an enviable safety record, with far fewer shutdowns due to accidents than for example, the United States. But accidents do occur, such as the leak of low-level radioactive waste at the

Tsuruga power plant in 1981 and the exposure of an official of the International Atomic Energy Agency to traces of plutonium earlier this year.

A key element in future plans is the construction of a huge fuel cycle facility for uranium enrichment, fuel reprocessing and low-level waste storage in Aomori Prefecture at a cost of one million million yen (£4,300 million). But this facility, for which approval was granted by the prefectural government in 1985, has yet to gain the unanimous approval of the local fishing cooperative and the start of construction has been delayed.

Fishing cooperatives wield considerable political power in Japan as do other blocks of rural voters who traditionally support the ruling party. Promises of Y177,000 million yen (£750 million) in contracts for local companies and 1,400 jobs have won approval for the project from other sections of the local community.

If the Aomori complex is completed on schedule in the 1990s, it will provide 30 per cent of Japan's enriched uranium requirements by the year 2000, and will be capable of reprocessing most of the spent

fuel that is now sent to French and British facilities. According to the report, a second fuel reprocessing plant will be built in Japan in 2010 to meet increased demand.

Low-level radioactive waste will be stored at Aomori in a plant with an eventual capacity of 3 million 200-fitre drums. It will be capable of dealing with all Japan's low-level waste produced by 2030 and beyond.

Greatest growth over the next 45 years is seen in establishing the fuel cycle. Expenditure is expected to amount to Y70,000 million million yen (£300,000 million) by 2030. The only note of restraint in this bullish assessment of the future of Japan's nuclear industry is in regard to fast-breeder reactors, commercial operations of which are predicted to start in 2020, ten years later than expected.

But a big question mark hangs over the locations of the proposed new plants. The report calls for the establishment of 20 new sites without clearly stating where they will be. Development of new siting technology is advocated so that nuclear plants can be placed underground, on the sea, and close to population centres. Clearly Chernobyl has not shaken the confidence of Japan's nuclear power planners.

David Swinbanks

Chernobyl

Experimental speculations

THE Soviet Politburo, apparently responding to a torrent of questions about the mysterious "unauthorized experiment" said to have been under way when the Chernobyl reactor accident occurred on 26 April, said last week that the power station crew was attempting to operate the reactor at a low power, below that for which it was designed.

From the beginning, Soviet statements have said that the Chernobyl reactor was operating at 7 per cent of full power at the time of the accident. Many reactor engineers in the West now consider that the most likely explanation of the Soviet statement is that those concerned were trying out some scheme for operating the reactor's housekeeping functions from the station turbine proper, and not from the stand-by diesel sets provided to guard against disconnection from the Soviet electricity grid.

While operating at full power, reactors are naturally able to deal with this "hotel" load from their own production of electricity, but the removal of fission product heat from a shutdown reactor requires an external source of power. Measurements of fallout from Chernobyl suggest that the reactor had been shut down for some hours before the first release of radioactivity began, which would suggest that the decay heat of the fission products

would by then amount to some 4 per cent of the total power, less than the 7 per cent quoted by Soviet sources.

Dr David Hicks, director of the UK Atomic Energy Authority's water reactor programme (chiefly concerned with the safety of pressurized water reactors) said earlier this week that such an operation, well outside the power range for which the Soviet RBMK reactors are designed, could well have made the Soviet reactor prone to the instabilities for which it is known, especially because a core which had been in use for 1.5 years would have accumulated such a load of fission products that the production of even a few per cent of full power by fission would have required that the control rods should be to a large extent withdrawn.

The occurrence of steam voids within the cooling system would, in these conditions, have created power excursions which it might have been difficult to control by means of the control rods, which move in narrow water channels where their free fall is impeded. Hicks emphasized, however, that his theory of what may have happened is only one of many.

Much of what is known of the Soviet reactors derives from three consultations in the mid-1970s when British and Soviet designers exchanged information about the RBMK and its British analogue.

French budget

Bleak prospect for researchers

THE French government research budget for 1987 is now more or less complete. No figures have been released, nor are they likely to be before September, but the indications are that the spending power of French scientists will at best be pegged at around the levels of 1985. There may also be redundancies, as the Prime Minister, Jacques Chirac, has ordered a 1.5 per cent across-the-board cut in government employment. There is hope, however, that the job losses will be partly compensated by a growth in the recruitment of young scientists, under a government scheme to counter youth unemployment.

The worsening prospects for French scientists, coming after the boom years of the early 1980s, were heralded by an 8 per cent cut in the science budget made in April, just a month after the new government came to power. The change shows

Terrorists strike again

Hamburg

THE terror against technology in West Germany continues. Following the killing of Siemens research manager Karl Heinz **Beckurts by terrorists of the Rote Armee** Fraktion (RAF), a bomb exploded at the Fraunhofer Institute for Laser Research in Aachen at 5 a.m. on Thursday last week. The total damage has not vet been estimated, but some sensitive machines seem to have been affected. In a letter found near the site, a "Fighting force Sheban Atlouf" admitted its responsibility for the attack. The institute, which is part of the Technical University of Aachen, is carrying out research only on the introduction and use of laser techniques for industrial and medical purposes, according to the head of the institute, Professor Herziger.

RAF struck again last Friday at 5 a.m. This time their chosen target was more in line with their announced aim of hitting military and nuclear research institutes. The bomb exploded outside the head-quarters of Dornier GmbH, owned by Daimler Benz, in Immenstaad. Only a wall and about 250 windows were damaged.

Police think that this may be the beginning of a series of bombings against what RAF calls the "Militärisch Industrieller Komplex". Last year, when some bombs exploded near institutes for biotechnology and gene research, the new aim of the terrorists became clear. In the underground newspaper Sabot, anonymous sources have announced that "harmless" people in various institutes will face assassination. Protection for such a wide range of imperilled people and institutes cannot be given. Scientists have a hard challenge to face.

Jürgen Neffe

how depressingly shallow-rooted was the science policy-making system instituted by the previous administration during its five years in power. Research, it seems, never became a proper political and administrative fiefdom, and now the parts of the old estate, the ministry of research and technology, have been scattered among the ministries from which they were first confiscated in 1981.

The result, according to one senior French scientist, is that there can no longer be a science policy in France. Rather, research will get the scraps of the budget that are left after the real political carnivores — the ministers responsible for police and defence, among others, in this government — have torn at it. Only then will the minister of research and higher education, the well-meaning physicist Alain Devaquet, have a chance to form a policy. The importance for research and technology of having a politically powerful champion (in the previous French government it was Jean-Pierre Chevènement, who led the largest single wing of the socialist party) has never been clearer. Without power, the budget determines the policy; with it, the reverse is possible.

The Conseil Supérieur de la Recherche et de la Technologie (CSRT), the independent group of high-level scientific advisers to Devaquet, is already well aware of the sea-change facing French science, but seems powerless to act. Having seen the outline budget for 1987, the Conseil has been forbidden by Devaquet to speak of it. The minister will present his budget, which given inflation and the April cuts would need a 6 per cent increase in current francs to retain the spending power of 1985, probably in September. Only then will CSRT, of which Devaquet is ex-officio chairman, be free to publish its "advice"

Nevertheless, François Kourilsky, the Marseilles immunologist and scientific president of CSRT, has dared to warn that any suppression of scientific jobs would have "long-term effects incommensurate with the economies achieved", and to demand that the government "finish and publish a research and technology policy" This may come with Devaquet's awaited presentation, but the feeling is now clear in France that science has returned to the doldrums of the 1970s. Then, ministers in the Délégation Générale à la Recherche Scientifique et Technique (DGRST) who were responsible for "coordinating" the research budget in the prime minister's office were renowned for their fine forward-looking speeches in the Assemblée Nationale - but for their almost total lack of power to influence real Robert Walgate events.

US-Japan trade

No easy end to chip war

Washington

An agreement is expected early this week in the long and increasingly bitter negotiations between Japan and the United States on semiconductor trade. The United States is seeking greater access to Japanese markets for US semiconductor manufacturers, and an end to "dumping" of Japanese semiconductors on international markets. As both legal and self-imposed deadlines loom, negotiations have entered what a spokesman for the US semiconductor industry termed "a period of trench warfare".

For more than a year, the US semiconductor industry has been pursuing a trade complaint against Japan over access to Japanese semiconductor markets. US chips now account for only 10 per cent of sales in Japan according to US industry figures, as opposed to 83 per cent of sales in the United States and 55 per cent of sales in Europe. In late May, US Trade Representative Clayton Yeutter worked out a framework for concluding the trade case, known as the 301 case after the section of the Trade Act of 1974 that covers unfair trade practices. Included in the framework is the resolution of two other complaints that Japanese companies are selling erasable programmable read-only memory chips (EPROMs) and 256 kilobyte dynamic random access memory chips (256K DRAMs) below their production costs. A preliminary judgement made last year by the Department of Commerce found Japanese companies guilty of dumping in violation of international trade agreements. But in early July, both sides reached a tentative agreement to drop the dumping cases so that negotiations in a comprehensive agreement could continue. Since June, US and Japanese negotiators have been trying to forge an agreement under Yeutter's framework, but so far without success. Without a final decision to stop the dumping cases this week, permanent dumping duties will be imposed on all imported Japanese EPROMs and 256K DRAMs.

Opening Japanese markets to US goods is not straightforward. Despite the power of the Japanese Ministry of International Trade and Industry, it cannot force Japanese companies to buy US chips. The Japanese government has offered to open a special office to assist foreign companies in making semiconductor sales.

Japanese semiconductor producers are large, vertically integrated companies that can subsidize losses in their semiconductor division to purchase market share, an option not open to generally smaller US firms. No agreement will

change this situation.

A document leaked to the Financial Times of London gave details of a working draft of the agreement. The United States would agree to drop its dumping cases. and Japan would try to increase US market share in semiconductors to 20 per cent. To prevent future dumping disagreements, the United States would request

WITH a self-imposed deadline of Saturday, 26 July for concluding the negotiations, Japanese representatives were no doubt surprised when the US team announced on Friday that negotiations had to stop at 1 p.m. The reason? The Trade Representative's office had scheduled its annual picnic for that day, and not even Washington's current heat wave was going to stop plans for a softball game during the picnic.

immediate consultations between the two governments. These consultations would be limited to 14 days, in contrast to the year it now takes to resolve dumping issues. If dumping is suspected, the Japanese government will encourage its industry to provide documentation for the legitimacy of its sales figures.

Even if an agreement is reached, chip prices in Japan will probably stay comparatively low, and US importers are likely to find "loopholes" - purchasing semifinished goods containing chips or buying chips at Tokyo discount stores. Nevertheless, Japanese companies do appear to be worried by the agreement. They find it blatantly unfair and one-sided, placing Japan at a disadvantage to South Korea, Taiwan and especially to US companies that will have access to Japanese production costs under anti-dumping agreements. Japanese industry sees this agreement as being largely beyond their control, having arisen out of the politically close relationship between President Reagan and Prime Minister Nakasone.

As talks moved into the eleventh hour, both sides seemed intransigent. Three US manufacturers complained formally to the Department of Commerce that Japanese companies were trying to cut last minute deals at bargain prices with US customers before signing an agreement. By 30 July a decision has to be made on the EPROM dumping case, and the next day President Reagan must announce what action he will take in the 301 trade case. As *Nature* goes to press, it is impossible to say what the likely outcome would be.

The US industry is frustrated by the current negotiations. It believes it has an open and shut case against the Japanese both for dumping and for closing their markets. Hopes for agreement may have given way to a desire for retaliation against Japan for its trade practices. But a comprehensive agreement is still the ultimate goal. At stake could be nothing short of the future of the US semiconductor industry. Joseph Palca & David Swinbanks

High-technology trade

Anger over supercomputer veto

OFFICIALS at the British Embassy in Washington hope that they can soon resolve "without major compromise" the difficulties of British academics in obtaining US-manufactured supercomputers. Intensive discussions have been taking place over an issue that last week sparked a debate in the House of Commons.

The trouble began when the University of London Computer Centre found that its purchase of a Cray I supercomputer had been blocked by US government regulations. A condition of sale of the supercomputer is that scientists from Eastern Bloc countries and China must not gain access to the machine. But the centre's director, Richard Field, says that although the scientific standards of work carried out on the machine will be monitored, it is not possible to police all the computer's users to ensure there are no scientists from proscribed countries among them.

What has really enraged British opposition politicians is that the computer the centre wants is second-hand and already in Britain; all that has been requested is its transfer from the Atomic Energy Authority's Harwell laboratory. That the United States can control the movement of a computer inside Britain is described by Liberal Member of Parliament Mr Paddy Ashdown, who initiated the House of Commons debate, as a "flagrant breach of British sovereignty". And it became clear during the debate that while this may be the first time US controls have hit academics, British high-technology companies have had difficulties with US government regulations for some time. Indeed, Ashdown claims that one British company was effectively driven out of business by US sanctions.

The US regulations come on top of the COCOM agreement that regulates the export of strategically sensitive goods from members of the North Atlantic Treaty Organisation and Japan. British companies that wish to export manufactured goods containing any US component (as do most electronic products) now find themselves having to apply for a licence from both the UK Department of Industry and the US Department of Commerce.

Ashdown's exhortations to take on the United States did not go down well with the government. The official response, from Minister of Information Technology Mr Geoffrey Pattie, was that "if we could compel the United States to withdraw . . . the problem could be eliminated easily, but we cannot . . . and US reaction to a direct and comprehensive challenge . . . cannot be predicted". Rather than accept the opposition view of British Prime Mini-

ster Margaret Thatcher's "craven subservience to President Reagan". Pattie dwelt on the overall advantages to Britain of commercial and scientific links with the United States — plus the new efforts to reduce that dependence by strengthening links with Europe in large-scale development programmes. Problems with the United States have to be dealt with by a "case-by-case" approach, he says.

This view is scarcely welcome to British Embassy officials in Washington who have to do the case-by-case negotiations and hope for a more general understanding. An agreement is needed soon if research at the University of London is not to be severely disrupted. The computer should be delivered next month according to the contract, on which a prepayment has already been made. If the computer is not in place by the end of the year, the contract will be void and the computer centre will have to do what it can to seek redress. Any decision will also have a bearing on a contract for delivery of a Cray to the Science and Engineering Research council's Rutherford Appleton Laboratory next year. Alun Anderson

Science Digest dies

Washington

Science Digest last week became the latest casualty of the turmoil hitting popular science magazines. Hearst Magazines, its publisher, announced that the September issue of Science Digest will be the last. The subscription list and licensing rights to the name have been bought by Time Inc., publisher of Discover, for an undisclosed sum.

The announcement came as a shock to editorial staff, who have been given a week to clear out their desks. Hearst had been trying unsuccessfully to sell the magazine for several months before finally deciding to cease publication, mainly because of a drastic fall in advertising revenues (see Nature 322, 99; 1986). Hearst expects to retain and reassign about a third of the 26 Science Digest staff.

Time Inc. also recently bought for \$6 million the logo and subscription list of Science 86, the popular science magazine published until last month by the American Association for the Advancement of Science; its readers will be offered Discover instead. Science Digest subscribers will be offered a choice of various Time publications. A spokesman for Time Inc. said that Hearst had already made the decision to cease publication of Science Digest before Time agreed to buy the subscription list: the Science Digest logo is not likely to be used.

-CORRESPONDENCE-

GAP protest over South Africa

Sir—We wish to bring to the attention of the scientific community the circumstances that led to the cancellation of the Third International Workshop of the Group for Aquatic Primary Productivity (GAP) scheduled for 29 April—4 May in Durban, South Africa.

GAP was established in 1980 under the aegis of the International Society for Limnology and the International Association for Ecology to provide a forum for oceanographers and limnologists studying theoretical and methodological aspects of primary production in marine and fresh waters. Successful GAP Workshops were held in Konstanz, West Germany, in 1982 and Haifa, Israel, in 1984.

When the International Committee of GAP accepted the invitation of our South African colleagues to hold the third workshop in that country, we were aware of potential problems. It was clear that some scientists, as individuals, would choose not to attend an event in a country whose governmental racial policies are morally repugnant to most, if not all, of us. This viewpoint is understandable and such a decision is the prerogative of each individual.

We did not expect, however, to be faced with a situation in which a significant number of our colleagues who had expressed their intention to attend the workshop were expressly forbidden to do so by their superiors or administrations. In at least one case, a young scientist was threatened with jeopardizing his future career if he participated in any capacity at the GAP meeting. As a result of such pressures, the number of prospective participants in the workshop became so limited that we were reluctantly forced to cancel the meeting.

GAP is a scientific organization affiliated to the International Council of Scientific Unions (ICSU). For many years, ICSU has striven to guarantee the freedom of bona fide scientific exchange. The Principles of Universality as formulated by the ICSU Standing Committee on the Free Circulation of Scientists are basic to all ICSU objectives and have been reaffirmed by the latest ICSU General Conference in Ottawa in October 1984. Actions that deny scientists' freedom to travel to legitimate scientific activities are a flagrant and dangerous violation of these principles.

Science is an international endeavour, unfortunately tainted by political realities. It behoves the scientific community to be vigilant in maintaining its rights of free exchange and circulation. The forced cancellation of the GAP Workshop has no impact on the South African government's racial policies and only serves to increase the isolation of our colleagues

who are largely counted among the liberalizing forces there. We can only caution the scientific community that, alas, this will not be the last encroachment upon the Principles of Universality and advise vigorous and early protest in future instances.

Tom Berman (Chairman, GAP International Committee)

Israel Oceanographic &Limnological Research Ltd, The Yigal Allon Kinneret Limnological Laboratory, POB 345, Tiberias, Israel

RGO move OK

SIR—The decision of the Science and Engineering Research Council (SERC) to move the Royal Greenwich Observatory (RGO) to the University of Cambridge is a historic decision, whose consequences are not fully realized by Nature. Your leading article (Nature 322, 1: 1986) belittles the SERC choice as being based on the unwillingness of RGO staff to travel north of the Trent. This point-scoring ignores the facts that ex-RGO staff hold positions at the Royal Observatory, Edinburgh (ROE) — there has been a good history of staff interchange between RGO and ROE — and that large numbers of the RGO staff spend a large proportion of their time working and living overseas on La Palma and elsewhere. Jerry Sellwood's pro-Manchester letter (322, 106; 1986) comments on the decision by raising issues irrelevant to astronomy, such as national policies of regional development and an alleged prejudice by everybody against Manchester.

In deciding to move RGO to Cambridge, SERC is consolidating one of the world's great centres for astronomy, bringing radio, theoretical and optical astronomy together with the instrument science and engineering on which the progress of astronomy depends. It is true that many RGO staff (including ourselves) and many British astronomers opposed the move, and that the University of Sussex's astronomy programme could be damaged, an issue that SERC should address in the future. But we believe that of the choices SERC set itself the decision to move to Cambridge is best for British astronomy as a whole.

We hope that the Secretary of State for Education and Science, taking proper account of the financial arguments, will stick with the clear scientific decision of SERC. Further vacillation would prolong the problems for RGO and British astronomy; surely astronomers in the United Kingdom now need to put this matter be-

hind them and move confidently into the twenty first century, getting on with the tasks at hand.

Japanese education

SIR-I would like to add to Alun Anderson's News item (Nature 321, 6; 1986) on Japanese education from the viewpoint of an undergraduate student. The University Council recently decided to increase the opportunity for applicants to take the university entrance examination with the aim of increasing the flexibility of the universities. But I wonder if it will not produce another worse result; to standardize the quality of students and to rank more clearly all of the universities. The educational industry will also gain power, worsening the situation we call "the examination war ordeal". Even now, many applicants choose their universities only for their name value, and after entering have no clear object of study. To solve these problems, the universities must be given more independence and autonomous rights.

The PhD glut ("overdoctors" or unemployed PhD holders) is another difficult problem. If one wants to get a post in a university, one must put up with years as an overdoctor because of the low staff turnover. Otherwise one must move to private enterprise. For this reason, I think, Japanese basic research cannot develop fully.

SHINJI HIRANO

Faculty of Science, Kyoto University, Kitashirakawa, Sakyo-ku, Kyoto 606, Japan

Alun Anderson replies: I agree with Mr Hirano. All state universities have traditionally held their examinations on the same day, effectively preventing anyone from applying to more than one state university in any one year, a situation that commits candidates to the uncertain task of selecting a university with a pass mark thought likely to match the candidate's likely examination mark. Universities are now to be divided into groups with examinations on different days. But this may not solve the problem of universities forming a hierarchy according to their pass marks. Kyoto University law school, for example, fears that in future all its candidates will take both Tokyo and Kyoto University law school examinations and all those accepted for Tokyo will go there. That could have the immediate effect of converting Kyoto into a "secondrank" institution.

Catching atoms in beams of light

The past few weeks' excitement about the trapping of atoms in laser beams is well justified; the applications of the technique could be exciting.

THE notion that it might be possible to trap an atom in a single beam of light is, of course, nonsensical. Atoms capable of interacting with light of specified frequency will sense what is called radiation pressure, and be propelled along in the direction of the beam. This is how newly formed stars clear a nearly empty space in their immediate vicinity and, for that matter, how the outer regions of all stars are prevented from gravitational collapse upon themselves. It is only natural that people should not hitherto have sought to trap single atoms in a single laser beam.

That diffidence will now have to be dispensed with. A group from AT&T Bell Laboratories, in a continuation of work by A. Ashkin going back to the early 1970s, has indeed been able to trap a large collection of sodium atoms in a single laser beam. The group now reports (*Phys. Rev. Lett.* 57, 317; 1986) that it has been possible to gather as many as 500 atoms into a volume no more than 10 micro-metres in dimension, which corresponds to the respectable density of 10¹¹ atoms per cm³.

But how can such a feat be accomplished? Steven Chu, J.E. Bjorkholm, A. Ashkin and A. Cable have been able to start from a great deal of expertise accumulated over the years at their own establishment as well as from the many successes in recent years with different kinds of traps for atoms, usually built around combinations of electrostatic and magnetic forces. Devices of that kind, mostly elaborations of the Penning trap, have been widely used in recent years for the spectroscopy of isolated, or nearly-isolated, atoms.

The essential requirement for success appears, however, to have been the suspension of conventional belief. In a companion paper (ibid. 57, 310; 1986), J.E. Pritchard et al. rehearse the case for believing that optical trapping is impossible — before showing that not to be the case. The principle is simple enough. In a coherent beam of light, the flux of momentum is represented by the Poynting vector, which is proportional to the vector product of the electric and magnetic field intensities (and thus directed in the direction of an ordinary light beam). By an extension of the nineteenth-century Earnshaw's theorem in electrostatics, it then turns out to be the case that the Poynting vector must be divergenceless across any closed surface that does not contain a source or sink for radiation, just as the divergence of the electrostatic force must be divergenceless over a surface containing no electrostatic charges.

In the optical case, what this seems to imply is that the force on irradiated atoms, which must be in the same direction as the Poynting vector, will also be divergenceless and thus could not be formed in such a way as to be directed inwards everywhere on some closed surface. Ironically, say Pritchard et al., Ashkin is one of those to have argued that Earnshaw's theorem is a bar to laser trapping for atoms, thereby "discrediting these proposals and discouraging any others". One way round the difficulty would be to use light intensities varying with time, a technique that works with radio-frequencies; a temporarily inward array of forces can, for example, be switched off when a sufficient number of atoms have been corralled into some other kind of trap. Doing this at the frequency of optical radiation would be a different matter.

The essence of what Ashkin's group has now done is to use a strongly focused laser beam whose intensity profile is far from uniform but, rather, gaussian, with the peak intensity along the centre. Moreover, the laser generating the beam is tuned to a frequency some way below the natural resonance frequency of the sodium line, with the result that the force on sodium atoms can be controlled at an arbitrarily low level. In these circumstances, the only forces on sodium atoms that matter are those between the electric field of the laser beam and the electric dipole moments which they induce in atoms exposed to them. The forces depend on the detuning of the laser beam, but not as critically as the scattering.

The result is that sodium atoms can be made to move towards the most intense part of a non-uniform laser beam. To be sure, the magnitude of this effect is greater as the frequency of the laser approaches the resonance frequency (which is the condition when scattering could be a nuisance), which implies that a trade-off must be struck between the closeness of the approach to resonance and the steepness of the gaussian profile. That, says Ashkin's group, accounts for trapping on the axis of the laser beam. Trapping in the axial direction depends on the rapidity with which the beam is focused in space.

The actual success reported by Ashkin's group hangs crucially, as is acknowledged, on the way in which it has been possible to

start with sodium atoms "cooled", again by the use of laser beams, to an effective temperature of a quarter of a millikelyin. The idea there, implemented in the past few years, is that it is possible to rob an atom of its translation velocity in the direction of a beam of light whose trequency is well-defined by means of the transfer of momentum that occurs on scattering. The trick is to arrange the difference of the laser and the resonance absorption frequency of the atom so that the Doppler shift works in the direction of cooling, but does not as easily allow the transfer of momentum to atoms which are already nearly at rest. But if this works in one dimension, why not arrange that three lasers at right angles should bring a whole package of atoms to near-rest? This arrangement, called "optical molasses" for obvious reasons, was demonstrated only last year. In the new experiments, a package of atoms trapped in such molasses is used as the sources of material to be trapped by the single convergent laser beam, suitably detuned.

For the time being, everybody seems too breathless to wish to speculate where the new development will lead. It is nevertheless remarkable that the lifetime of a package of some hundreds of sodium atoms in such a trap can be as much as several seconds - virtually aeons by the frequency of the resonance absorption line. The lifetime of the trap is limited, for practical purposes, by the residual scattering of light by the atoms in the trap, from which they gain energy and an increased capacity to escape. One little refinement is that, according to Ashkin's group, it is possible to move the package of trapped atoms bodily from place to place, which is why AT&T Bell Laboratories, public relations people have coined the term "optical tweezers".

So what happens next? The insatiable curiosity of spectroscopists is only the most obvious suitor of the new device. The substantial density of atoms that seems to have been achieved suggests that it should be possible almost directly to simulate astrophysical processes in, for example, molecular clouds, especially if there is a chance of using the tweezers effect to mix together different materials. But, inevitably, there will soon also be better traps. Pritchard *et al.* have thoughtfully given no fewer than three recipes that will no doubt be quickly followed.

John Maddox

Pattern formation

Descartes and the fruitfly

from Geoffrey North

In recent years remarkable advances have been made in elucidating the developmental biology of the fruitfly Drosophila melanogaster, but despite the cloning and intensive analysis of many of the genes controlling morphogenesis, we still do not understand the processes of pattern formation in mechanistic detail. The evidence of a recent meeting*, however, suggests that this goal may at last be in sight. Perhaps the most telling signs of this are the links that are emerging between a complex and rapidly expanding set of data on the genetic control of embryonic segmentation on the one hand, and a theoretical model that can simulate many of the observations on the other.

The meeting also provided what seems likely to be the first identification of bona fide developmental morphogens, which define the anterior-posterior axis of *Drosophila* embryos. A gene implicated in the establishment of dorsal-ventral polarity has turned out to encode a serine protease, which as I shall explain may help to suggest a precise mechanism of pattern formation along this axis. And intriguing evidence was presented that these orthogonal axes might function like a Cartesian coordinate system, their points of intersection specifying different pattern elements at particular positions of the embryo.

Anterior-posterior axis

The polarity of the anterior-posterior axis of an insect is manifested both in the sequence of segments along its body and in the pattern within an individual segment. Various experiments suggest that this originates in localized morphogentic centres laid down in the egg from the onset of development. For example, the egg of the leaf-hopper Euscelis contains at its posterior end a ball of symbiotic bacteria, which can be experimentally moved within the egg. Such manipulations induce the development of posterior structures at inappropriate positions along the body axis, presumably because of cytoplasmic determinants carried with the ball of bacteria. Perhaps more dramatically, the ultraviolet irradiation of one or other pole of eggs of the midge Chironomus leads to the development of either double-headed or double-abdomen 'monsters', in which the untreated pole has apparently undergone a mirror-image duplication. On the basis of these and other experiments Sander' postulated that two gradients. one from either end, set up the anteriorposterior pattern of developing insects.

It has not, however, been clear how these striking results could be taken much further, so to bring the powerful techniques of classical and molecular genetics to bear on the problem Christianne Nüsslein-Volhard and collaborators (Max-Planck Institute, Tübingen) have attempted to reproduce the observations with Drosophila, which with a relatively small egg is less amenable to physical manipulation. They have succeeded, in a series of experiments involving various combinations of allowing cytoplasm to escape from the embryo through holes punctured at specific positions through the egg-case and transplantation of cytoplasm from one region to another'. For example, loss of cytoplasm from the anterior end causes loss of head structures and the development at the anterior pole of structures such as the telson normally only found at the posterior pole. If, in addition, posterior cytoplasm is transplanted to the anterior end the result is an embryo consisting of two abdomens arranged in mirror-image symmetry.

The phenotypes produced in these experiments can be reproduced by certain 'maternal-effect' mutations, in which the inability of the mother fly to make a wildtype gene product leads to the mutant embryonic phenotype. Thus bicoid mutants lack head structures (Nüsslein-Volhard) and oskar mutants lack an abdomen (R. Lehmann, Max-Planck Institute, Tübingen). Cytoplasm from the appropriate end of a wild-type embryo can rescue these mutants if injected into a specific region along their body axis, and in the case of bicoid mutants injection at the wrong site causes ectopic head development. The bicoid-oskar double mutants are particularly revealing: they lack both head and abdomen, and consist of juxtaposed posterior terminal structures which seem to be a kind of 'groundstate' made in the absence of information to the contrary. If such mutants are injected with wild-type cytoplasm from the anterior or posterior pole it is possible to correct one or other mutation, generating single mutant phenotypes in either normal or inverted orientation, depending on the end into which the cytoplasm is injected.

These results lead to a picture of mutually antagonistic determinants localized at either end of the egg with long-range effects on the nature and polarity of structures formed during development: whether they really generate formal 'gradients' is not yet clear. The bicoid

gene, which is located within the Antennapedia complex of homoeotic and segmentation genes, has been cloned, and Nüsslein-Volhard's in situ hybridization experiments show that it encodes a transcript localized at the anterior pole of the egg, presumably transported there from the transcriptionally active nurse cells to which the egg is connected.

The bicoid gene, therefore, has all the features of a gene encoding a developmental morphogen. The situation for oskar appears somewhat more complicated, for together with a small set of other maternal-effect genes, it seems to generate a signal at the posterior end that is transported anteriorly, where it has its effects on zygotic gene expression. In a model put forward by Hans Meinhardt (Max Planck Institute, Tübingen), a single gradient of maternal information is interpreted by the sequential activation along the anterior-posterior embryonic axis of the zygotic 'gap' genes, mutations of which cause the loss of large contiguous groups of segments. The results with bicoid and oskar are more consistent with Sander's proposal that there are morphogenetic centres at both poles of the embryo, but the 'gap' phenotype of oskar mutants supports the suggestion that the gap genes are the next stage in the developmental hierarchy after maternally expressed genes.

In Meinhardt's model, the gap genes (which he prefers to call cardinal genes) play a central part in initiating both the periodic pattern of segmentation and, via the homoeotic genes they are postulated to regulate, the sequential pattern of segment specification. Interest in this model has been fuelled by recent results that bear out several of its non-trivial predictions. For example, although different gap mutations delete large, overlapping regions of the embryo, Meinhardt predicted that they would be expressed in non-overlapping regions about half the length of the affected region — and in the case of Krüppel and hunchback this has turned out to be just the case (H. Jäckle, Friedrich Miescher Institute, Tübingen). Also confirmed has been the prediction that the loss of a given gap gene would cause the expression of the neighbouring gene to spread into its domain (Jäckle). In the model the gross non-autonomy of gap genes results from the central importance of the borders between the domains of gap gene expression in organizing the expression of the next set of genes in the postulated hierarchy, the pair-rule genes (the first to have a periodic pattern of expression): the loss of one gap gene eliminates two borders and hence a region of the embryo twice as long as that in which it is expressed.

Data on the expression of the segmentation genes of *Drosophila* are being obtained at a tremendous rate, and some

^{*5}th EMBO workshop on the molecular and developmental biology of *Drosophila*, Kolymbari, Crete, 21–29 June 1986.

of these have been discussed recently in News and Views. The main focus at present is to obtain clues as to how the genes interact by studying the effects of mutations in one gene on the expression of another. With so many genes apparently involved, however, the interpretation of such experiments is unlikely to be simple, and it was notable at the meeting that most of the experimentalists averred that they found Meinhardt's model a helpful framework in which to try to interpret their results. The film Meinhardt showed at the meeting of computer simulations based on his model demonstrated that it can closely simulate the evolving patterns of segmentation gene expression in wild-type and normal embryos that are observed experimentally.

Dorsal-ventral axis

A further set of maternal-effect mutations affects pattern-formation along the dorsal-ventral axis of the Drosophila embryo. Recessive mutations in at least 10 genes cause dorsalization of the embryo, and a series of experiments7.8 reviewed recently in News and Views9 has led to a model for the establishment of dorsalventral positional information by a morphogenetic product generated by these genes. One of this set, snake, has been cloned and sequenced, and encodes a protein with all the features of a serine protease (R. Delotto, University of Geneva). This is an exciting result, for serine proteases are made as inactive precursors activated by specific proteolytic cleavage, and in blood clotting and complement fixation chains of specific serine proteases are arranged in a cascade to amplify an initial signal in such a way as can readily be envisaged to be applied to the more glamorous problem of pattern formation. Both blood clotting and complement fixation generate products tightly localized in space close to the initial signal: the intriguing prospect is that such a signal, probably at the ventral pole, initiates a cascade of reactions which converts it into a set of coordinates along the dorsal-ventral axis. If this is true, other dorsalization genes should turn out to encode serine proteases.

Although the issue has been controversial, it is now generally accepted that during development the anterior-posterior axis of the Drosophila embryo is divided into polyclonal units called compartments, defined by the expression of sets of 'specifier' genes that determine their pathways of development. Whether the dorsal-ventral axis is divided into compartments analogous to those along the anterior-posterior axis is unclear. That this may be the case is suggested by recent work on another gene of the Antennapedia complex that has recently been cloned, zerknullt (zen)[™]. Mutations of this gene affect the differentiation of

A bacterial haemoglobin

from M.F. Perutz

HAEMOGLOBIN was believed to be a protein that evolved in eukaryotes, but a report elsewhere in this issue (Wakabayashi, S., Matsubara, H. & Webster, D.A. Nature 322, 481; 1986) describes a bacterial haem protein from Vitreoscilla that combines with molecular oxygen and has an amino-acid sequence with features characteristic of the globins.

There are only two amino-acid residues that are common to all the globins: a histidine that forms a covalent link with the haem iron; and a phenylalanine in position 1 of the loop made by helices C and D which wedges the haem into its pocket. All other residues are replaceable, but in 33 specific positions replacements are restricted to non-polar residues (Perutz, M.F., Kendrew, J.C. & Watson, H.C. J.molec. Biol. 13, 669; 1965).

The haem protein of Vitreoscilla does contain non-polar residues at almost all these positions, and it shows marked homology with the haemoglobin of the leguminous nodules of lupins, whose globin is encoded by a gene in the plant, rather than the symbiotic bacterium Rhizobium where the haemoglobin is concentrated. Most haemoglobins contain a histidine in a position distal to the haem, but the α -chain of the oppossum is an exception and contains a glutamine in-

stead. The alignment of the Vitreoscilla sequence by Wakabayashi et al. suggests that it also has a distal glutamine whose amino group could form a hydrogen bond with the bound oxygen, just as the distal histidine does in myoglobin (Phillips, S.E.V. & Schoenborn, B. Nature 292, 81; 1981). Homology between Vitreoscilla and other globins extends to helices B, C, E, F, G and H; helix **D** is missing as it is in the α -chains of mammalian haemoglobins, and homology ends at the A-B corner. The first 11 residues show no homology with the A helix, but this helix is unimportant because it is not in contact with the haem.

What is the function of this haemoglobin? The haemoglobin content of Vitreoscilla increases almost 50-fold when the oxygen concentration of the growth medium falls below 10 per cent of atmospheric. Apparently, species of this genus live in oxygen-poor environments; possession of the haemoglobin helps them to absorb oxygen for their aerobic metabolism. Is this an example of divergent or convergent evolution or of gene transfer from eukaryotes? Who can guess? We were not there when it happened.

M.F. Perutz is at the Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2Q11.

dorsally derived embryonic tissues. Analysis of the cloned gene shows that it contains a homoeo box and is expressed in dorsal tissues of developing embryos. The evolution of the pattern of zen expression along the dorsal-ventral axis during development is reminiscent of genes such as Ultrabithorax that are expressed in a compartment-specific manner along the anterior-posterior axis, suggesting that zen may be involved in the specification of a dorsal-ventral compartment.

A Cartesian coordinate frame?

Meinhardt has suggested that the points on the surface on an insect embryo where dorsal-ventral and anterior-posterior compartment boundaries intersect might specify the positions of the imaginal disks that later in development generate the adult cuticle structures. Intriguing evidence that this could be true was reported by W. Gelbert (Harvard). Mutations of the decapentaplegic gene of Drosophila cause the loss of pattern elements derived from the centres of imaginal disks. Gelbert explained that clonal analysis shows that a normal decapentaplegic gene is required only in cells that abut the anterior-posterior compartment boundary of a disk for normal development.

Furthermore, using the cloned gene it has been found that decapentaplegic is expressed in a dorsal region of the embryo, later splitting into two stripes running along the anterior-posterior axis on either side of the embryo just where the two lines of imaginal disks later develop. So it could be that these stripes define dorsal-ventral compartment boundaries, and the spatial cue for disk formation is where they cross anterior-posterior compartment boundaries. I am sure that the founder of analytical geometry, René Descartes, would be pleased by this elegant application of his system of spatial coordinates to biological pattern formation.

Neural models

Networks for fun and profit

from James A. Anderson

Knowing how the brain works is intrinsically interesting and could be practically useful. There have been many attempts to make artificial systems compute the way we seem to. Recently, there has been a renaissance of interest in what have been variously called neural models, brain models, neural networks and connectionist models. Two recent papers^{1,2} provide examples of how some important practical problems turn out to be well suited to computations based on neural networks, and applications using these networks may appear in the near future.

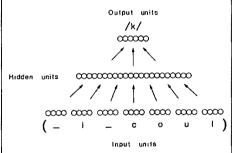

Connectionist systems were originally proposed as models for brain organization and for psychological functions such as association, concept formation and word recognition. But there has been a change in the past year — an adequate brain model must be able to compute something. It seems that even at their current state of development, the things that connectionist models compute effectively are now of interest to many scientists and engineers with practical problems.

There are several variants of connectionist models, but all have similar structure. They assume that there are a very large number of simple processing elements arranged in parallel arrays. Processing elements can either be simple Boolean devices with two allowable states (for example, on or off) or they can have continuously graded activity. Elements in the same group can be coupled together or can be joined to elements in other groups by connections with modifiable strengths. This interconnected system is largely based on the architecture of the mammalian cerebral cortex, with varying degrees of oversimplification: the properties of the elements are inspired by the properties of neurones and those of their modifiable connections by synapses.

There are two distinct aspects to the functioning of a connectionist system. First, the strengths of the interconnections must be specified. One way this can be done is by having the network learn a set of training activity patterns so it forms the appropriate connection strengths based on a learning rule. Most learning rules are variants of an idea proposed by Donald Hebb in 1949, that a connection strength is changed based on the simultaneous occurrence of activity on both sides of the connection. Another way is by simply knowing what the strengths should be to compute what it is you want to know. This is possible for some well-defined problems, and has the great advantage that a slow and sometimes unreliable learning process can be bypassed.

Second, when the connections are formed, the network must be provoked to perform the desired computation. An input pattern of activity is provided to start the system, then the initial pattern, through the interconnections, modifies itself and affects the activity of other connected elements to form a new pattern. This process may repeat for a number of steps until the network stabilizes, or it may run continuously. If the system works properly, the new patterns contain the results of the computation.

One example of a new application of networks is NETtalk, a program which converts text into spoken English (reads) developed by Terrance Sejnowski and Charles Rosenberg^t. Reading printed text

Schematic drawing of the network architecture for NETtalk. Input units are shown on the bottom of the pyramid, with 7 groups of 29 units in each group. A 29-unit group corresponds to a single letter, giving rise to a 7-letter window into the text. Each hidden unit in the intermediate layer receives inputs from all the input layers in the bottom layer, and in turn sends its output to all 26 units in the output layer. An example of an input string of letters is shown below the input groups, and the correct output phoneme for the middle letter is shown above the output layer. For 80 hidden units, which were used for the corpus of continuous informal speech, there was a total of 309 units and 18.629 weights in the network. (Figure and caption from ref.1.)

is typical of the rule-based systems used by humans. There are important rules and regularities in English spelling, but there are also many exceptions to the rules. Sejnowski and Rosenberg used samples of English text with the conversion of that text into phonetic symbols. As they then knew the input strings of characters and output strings of phonemes for many examples, they could modify connection strengths using an effective learning algorithm called back propagation, developed by David Rumelhart, Geoffrey Hinton and Ron Williams3, and independently by David Parker and by Yann Le Cun3.

This algorithm is able to learn effectively when there are several layers of modifiable connections between input and output. It is an error-correction technique that sends corrections 'backwards' from the output (where we can measure the error) to earlier layers with the appropriate strengths. NETtalk looks at seven input characters at once to generate an output phoneme, as pronunciation of a particular letter is strongly dependent on context. There are three layers of processing elements: an input layer, an output layer and a layer of 'hidden units' between input and output. After about a dozen hours of computer time on a VAX superminicomputer, the program was 'speaking' correctly more than 90 per cent of the words encountered in the input text. When a speech synthesizer was connected to the output, it generated quite understandable speech with occasional, usually minor, mispronunciations.

This simulation is much more than a curiosity. Sejnowski modelled the name of the simulation, NETtalk, after a commercial product of the Digital Equipment Corporation called DECtalk, a complex system developed over several years which speaks the words and characters appearing on a computer terminal. Sejnowski and Rosenberg, starting from zero, took less than three months to develop a functioning system that can do some of the same things.

A second example is the recent work of John Hopfield and David Tank². Hopfield had written two influential papers^{6,7} that pointed out some similarities between neural network computations and some problems in solid-state physics, for example, spin glasses, with a similar mathematical structure. He showed that the essence of the dynamics of a network computation in many cases is that the network is trying to put the state of the system in a minimum of what can be interpreted as an energy function in a physical system. This means that many of the powerful analytical tools available in physics can be carried over bodily to neural networks and might help towards understanding brain function.

The new paper by Hopfield and Tank² shows how a neural network can be applied to a practical problem that seems remote from brain function. They discuss the use of network model to estimate the answer to the 'travelling salesman' problem, the best-known example of a set of problems called np-complete by computer scientists. Like many good problems it is simple: a travelling salesman is given a number of cities to visit on his route. What sequence of cities gives the shortest total travel distance? To be certain the shortest route has been found, it is necessary to compute the distance for all possible routes. As the number of cities increases, the number of combinations to check

grows exponentially, and it rapidly becomes impractical to find the best solution. This problem is related to many optimization problems such as minimizing costs and maximizing efficiency.

Hopfield and Tank² show that a suitably designed neural network can compute a good estimate of the best solution. When checked, it is not the best solution but it is quite close to the best and can be computed quickly. Their technique is to arrange the system so that only allowable solutions to the problem can occur. For example, if the city is visited eighth on the circuit, then no other city can also be visited eighth. When one city is chosen for that position on the trip, it inhibits all the other candidates for the eighth position. No city can be visited twice, so if a city is chosen for one position on the route, it inhibits its potential appearances in other positions on the route. Hopfield and Tank constructed the connection strengths and the energy function so that as the state of the network evolves, the states corresponding to routes with small total distance grow at the expense of other routes. If the initial state of the system is random, the final state of the system corresponds to a route with a small total distance and is an allowable route. If the computation is repeated a few times with different initial states, the best solution is close to the actual solution of the problem. For many practical applications, this is good enough to be satisfactory.

But special algorithms for this problem are able to get better and faster estimates. and DECtalk works. So why bother with NETtalk and its potential descendents? One reason is that these two quite different problems are solved with techniques that are basically that same: interconnected sets of simple elements coupled with modifiable connections. Special-purpose hardware built to make one compute quickly will make the other compute quickly as well. Also, the algorithms for a network computation are highly parallel, that is, all the elements are computing their outputs simultaneously. Network computations are therefore well suited for parallel computers. For example, optical hardware, with its high speed, low precision, parallelism and high interconnectivity, is an excellent match for the requirements of network computations. Several groups are now building specialpurpose parallel hardware specifically for networks.

Once the hardware becomes available. it can be used for a wide range of problems, from optimization to learning rules for natural language, with only minor changes. Connectionist models may not give the best or fastest answer to any particular problem but will come up with a pretty good answer quickly. It is this potential flexibility and speed that makes practical applications so attractive. The brain may show similar computational flexibility and power for similar reasons.

Physiology

Chloride ions and cystic fibrosis

from Maynard Case

Cystic fibrosis, a lethal inheritable disease, seems to involve defective transport of chloride ions across epithelia. Such a defect could be caused by an alteration in the number, characteristics or regulation of Cl- channels in the plasma membrane of epithelial cells. Three recent articles1-3, one of which appears on page 467 of this issue', suggest it is the regulation of Cl-channel activity that is at fault.

The conventional electrophysiological studies on sweat gland ducts' and airway epithelia⁵ (which are both affected in cystic fibrosis) point conclusively towards the involvement of decreased Cl- transport in the pathophysiology of this disease. The nature of this transport defect has now been studied independently by Welsh and Liedtke^{1,2} and by Frizzell et al.³ using patch-clamp techniques.

The two groups have studied primary cultures of tracheal epithelial cells from normal subjects and cystic fibrosis patients and have recorded both from intact cells and excised, inside-out membrane patches. They both describe the presence of Cl -- selective channels on the apical membrane of these epithelial cells but under similar experimental conditions, Welsh and Liedtke observe only one type of channel whereas Frizzell et al. detect two channels. Also, the channel described by Welsh and Liedtke seems to be insensitive to Ca2+ but those described by Frizzell et al. are both Ca²⁺-sensitive.

Despite these apparent and important differences in the characteristics of the channels, which might perhaps reflect differences in tissue culture technique, the major findings of the two studies are similar. First, during recording from intact cells, Cl--channel activity can be elicited by adrenaline or cyclic AMP in normal but not cystic fibrosis cells; and second, in excised patches, the biophysical properties and kinetic behaviour of the channels are identical in both cell types. This suggests that the problem in cystic fibrosis relates not to the presence or absence of the Cl⁻ conductance but to the regulation of this conductance by a cyclic AMPdependent process.

Although both studies describe differ-

ences between normal and diseased cells only about half the intact normal cells respond to stimulation by opening Cl -channels whereas all excised patches from normal and diseased cells show activity. This may indicate active inhibition of the Cl channel so that excising the patch or stimulating the cell removes some sort of brake. If so, perhaps the brake-release mechanism is at fault in cystic fibrosis. Alternatively, there could be two populations of epithelial cells in normal subjects, but only one in cystic fibrosis patients.

These articles refocus our attention on the pathway generating cyclic AMP, but as adrenaline causes the normal accumulation of cyclic AMP in cultured airway cells from cystic fibrosis patients, presumably the defect lies downstream from cyclic AMP generation itself. If a cyclic AMP-dependent pathway is involved in the disease, this may help to explain the effects of the disease on the pancreas another prime target.

Secretion in the pancreas occurs across both acinar and ductal epithelia. Whereas the former is controlled by Ca'-mobilizing agonists (cholecystokinin and acetylcholine), secretion across the ducts is controlled by secretin, which seems to act exclusively via cyclic AMP. Hence these studies on airway epithelia support the hypothesis that pancreatic ductal secretion is faulty in the disease. However, as cystic fibrosis is thought to be associated with defective Cl secretion, it has always been a problem to explain why an epithelium lining the pancreatic ducts that secretes HCO₁, rather than Cl . should be affected (although this HCO, secretion is Cl-dependent). If the fault lies in the regulation of the anion channel rather than the channel itself, as this recent work suggests, this objection is overcome.

Population biology

Genetic management in zoos

from Andrew F. Read and Paul H. Harvey

Animal populations in zoos tend to be small and, therefore, particularly susceptible to the loss of genetic variability. Such losses can have harmful effects on the fitness of individuals as well as reducing the evolutionary potential of populations1. Interest in the genetic management of zoo populations has recently taken on a fresh urgency² because of the increasing realization that captive breeding programmes are essential to prevent many species from becoming extinct. A new 13-chapter report, written by about 40 zoo managers, geneticists and population biologists3, introduces rather than solves many relevant problems, but should provide an important framework for future research.

The increasing size of the human population is causing large-scale degradation of tropical and temperate ecosystems that support most of the world's wildlife. If the human population achieves zero population growth in about 100 years, as some demographic studies forecast^{4,5}, and then begins to decline, it would take several centuries before viable populations of many animal species could be restored in the wild. Given such dismal prospects for the world's fauna, zoos must be prepared to act as stewards or as 'arks', to use the metaphor of Soulé et al.3. These authors point out that technical improvements may eventually provide other ways of maintaining populations (for example, by regenerating organisms from preserved zygotes). But in the meantime, they argue. about 2,000 species of terrestrial vertebrates, including 160 primates, 100 large carnivores, 100 artiodactyls, 800 birds and several hundred amphibians and reptiles, may have to be captively bred to save them from extinction.

The preservation of genetic diversity is becoming a primary goal of many captive breeding programmes. Juvenile mortality in captive species has been linked to the loss of genetic diversity after inbreeding. Similarly, the low level of heterozygosity in South African cheetahs Acinonyx jubatus jubatus may underlie the great difficulty these animals have breeding in captivity, their high degree of juvenile mortality and their extraordinary sensitivity to pathological viruses. Loss of genetic diversity could also limit the potential of a population to adapt to new environments when reintroduced to the wild.

If maintenance of genetic variation is to be a central aim of management, how should we measure it? Electrophoretically detected protein variation has been used to estimate the overall extent of genetic variation within populations. For example,

such tests identified the low level of heterozygosity in cheetahs⁸. Allozyme surveys can be used to distinguish outbred populations from genetically homogeneous inbred populations, but heterozygosity at a few protein-coding loci is not necessarily a good estimate of the overall genomic heterozygosity of an individual. For example, the average number of loci examined in routine electrophoretic surveys is about 20. As Hedrick and coauthors point out3, if the expectation of heterozygosity is the same at all loci; if the loci segregate independently; and if the 20 loci are examined from a pool of 1,000, the correlation, between heterozygosity for those loci and overall heterozygosity is only 0.14.

Furthermore, heterozygosity may be an

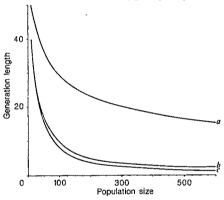

Fig. 1 Combinations of target population sizes and generation lengths required for a species to retain 90 per cent of the genetic variation of the source population for 200 years, given an exponential growth rate of 1.0 and founder population sizes of 10 (a), 20 (b) and the target number of individuals $(c)^3$. Species with long generation times can be maintained with fewer animals, and the size needed can be decreased dramatically by increasing the number of founders used to initiate the captive population.

insufficient measure of genetic variation. Allendorf argues that useful allelic diversity is largely caused by rare alleles that are likely to be lost early in a captive breeding programme, with only a minimal effect on heterozygosity3. Although heterozygosity is a good measure of the ability of a population to respond to selection in the short term (the first few captive generations), the number of alleles may be a more important indicator of the potential long-term response under continued selection. Thus, both high heterozygosity and high allelic diversity are desirable in species under consideration for reintroduction programmes. The problem, then, is to determine the number and distribution of alleles. Electrophoretic

techniques provide somewhat conservative estimates, whereas DNA sequencing is more accurate but more costly.

How many individuals of each endangered species should be kept in zoos? This depends on the amount of genetic variation to be maintained in the captive population over a specified amount of time. Soulé and co-authors set themselves the theoretical problem of keeping a captive population which, after 200 years, retains about 90 per cent of the genetic variation found in the original wild population3. This, they think, is the intuitive threshold between a tolerable loss of heterozygosity and potentially damaging homozygosity that provides enough time for the biotechnology to develop that will be necessary to maintain and regenerate species from preserved eggs, zygotes or tissues. Their model assumes random breeding in groups, equal sex ratios, non-overlapping generations and Poisson-distributed family sizes. The target captive population size depends on generation time, population growth rate and the number of interbreeding founders. The combinations of population sizes and generation lengths required for species with an exponential growth rate of 1.0 are shown in Fig. 1. Given that a major aim is to use resources as efficiently as possible, zoo managers are faced with the prospect of minimizing the number of individuals of each species held, while at the same time attempting to retain genetic variability within the captive population.

For a fixed number of founders, species with longer generation times require smaller target captive population sizes, because under the assumptions of the model there is loss of alleles only during reproduction. But the required target population sizes can be very sensitive to the number of individuals taken from the wild. For the values shown in Fig. 1, a large decrease in the target population size can be achieved by increasing the number of founders, at least up to 25 animals. (Fewer founders are needed in species with high population growth rates but, even with the highest rates of growth, the founder population should still be above six, otherwise more than 10 per cent of the genetic variability will be lost in the first generation.) Ideally then, captive propagation plans should aim to start with more than 20 founders (although the actual number depends on the rate of growth and generation time of the species in captivity), increase to the eventual population size in few generations (so that the effects of genetic drift are minimized and to ensure survival of the species in captivity) and then, if possible, artificially delay reproduction. Soulé and co-authors consider that breeding programmes should aim to maintain an effective population size of 200-300 individuals for more species.

Fig. 2 Przewalski's horse

The number of founders and reproductive rates of several endangered species currently in captive breeding programmes falls well short of those guidelines. The population of Przewalski's horse (Equus caballus przewalskii; Fig. 2), for example, has a growth rate of 0.1 and is derived from only 13 founders. According to Soulé's model there is no target population size which will allow the retention of more than 90 per cent of the original genetic variability.

Should populations be divided? Subdivision helps to protect populations from total extinction by epidemics or local disasters, and for this reason alone it is desirable to have more than one captive group of any endangered species. Foose and co-authors also point out that, if at least one breeding individual per generation is transferred between groups and there is no differential mortality according to genotype, the entire captive population is nearly equivalent to a single interbreeding unit

Which animals should be chosen for captive breeding programmes? This is by no means a trivial question. The choice of individuals for reintroduction to the wild must take into account the extent to which they are likely to be adapted to local conditions. For example, the Tatra Mountain ibex Capra ibex ibex became extinct in Czechoslovakia but was successfully reintroduced from Austria. Subsequently, C. i. aegagus from Turkey and C. i. nubiana from Sinai were added to the Czech herd. The resulting hybrids rutted in the early autumn, rather than in the winter as the local ibex did, and their young were born in February, the coldest month of the year. As a result the whole Czech population became extinct10.

Major problems facing captive breeding programmes include relaxation of natural selection and inadvertent selection for domestication. For example, selection for ease of handling may result in loss of predator escape behaviour. Frankham and co-authors conclude that selection in captivity can be minimized by adopting breeding plans designed to maximize genetic diversity'. As well as maximizing the number of founders, rapidly expanding and then subdividing the population, they suggest equalizing the genetic contribution of each of the founders to subsequent generations by manipulating family sizes. The only active selection they advocate is to cull animals with specific deleterious traits and outliers in morphological or fitness measures.

Any other forms of artificial selection must be justified. Selection for captive breeding success is clearly appropriate for rare species not yet capable of selfsustaining reproduction in captivity. In some cases it may be desirable to select against certain genotypes. Captive populations of Przewalski's horse, for example, have had genetic inputs from 12 wildcaught Przewalski's horses and one Mongolian domestic mare. The historical distribution of the breeding lines has resulted in two-thirds of the current population having genetic inputs from this mare. An interim breeding plan aimed at purifying the captive population by allowing matings only between animals lacking genetic input from the mare has begun. This selection will, of course, turther reduce the genetic diversity of the species. In the case of the Speke's gazelle Gazella spekei, selection for inbreeding tolerance was applied. This was inevitable because the captive population was facing serious inbreeding problems, had very few founders and no opportunity for input from the wild.

Hedrik and co-authors add a note of caution'. Successful reintroduction, they say, is more likely when genetic variation in a captive population is maintained in the form found in natural populations. The maintenance of the breeding and social structure found in the wild may be more important for a species than a programme designed only to retain maximum genetic diversity.

Several simulation models have been developed to assess the interacting effects of such competing management goals. These models assign a genotype to each founder and then, using pedigree data and demographic characteristics of popula-tions, subject the 'colony' to various management plans. One such computer experiment, reported by Dyke and coauthors', uses data from a real colony of captive rhesus monkeys to test the idea that removing some individuals from a single age group (usually early in life) and removing all older breeders with low reproductive rates would increase the

GIANT tube worms (Lamellibrachia sp.) have been found in Japan's deep-sea back yard, 1 km from the east coast of the Izu Peninsula, at a depth of 1,160 m. The worms, 60-70 cm in length, occur alongside giant clam (Calyptogena soyoae) colonies, the largest of which spans 200 by 80 m. Methane levels reach 10,000 at per litre a few centimetres above this 'vent' community which is aligned along a major fault associated with subduction of the Philippine plate beneath Japan. Photograph taken in May/June 1986 during a survey by the Japan Marine Science and Technology Center and the Ocean Research Institute, University of Tokyo. David Swinbanks

productivity above that obtained when individuals were removed at random. Productivity increases with minimal effects on the genetic variability of the population. The implementation of increased population growth rates need not, therefore, add significantly to the problems of genetic management.

Ultimately, the biological problems so carefully brought together in this volume may be dwarfed by financial and political

constraints. At present, zoos can sustain around 925 species of terrestrial vertebrates with captive population sizes of more than 250, far short of the 2,000 species that may need to be accommodated. This time around, the ark may be very crowded.

Archaeology

A new chronology for the French Mousterian period

from Paul Mellars

THE classic sequence of 'Mousterian' industries recorded within the cave and rock shelters of southwestern France represents an important record of Neanderthal man, but the dating has been controversial. Dating of the Le Moustier site by thermoluminescence techniques, reported on page 452 of this issue', provides one of the first well-documented points of reference for the chronology of the sequence and therefore will require reanalysis of climatic and human changes during this period.

The time range of the Mousterian (broadly from 40,000 to 115,000 years before present (BP) — coinciding with the earlier part of the last glaciation) puts it effectively beyond the range of dating by means of conventional radiocarbon techniques, and even the refinements of the new accelerator mass spectrometer techniques of "C measurement are unlikely to extend for more than 10–20,000 years into the most recent part of the period².

All attempts to construct a detailed in-

ternal chronology for the Mousterian have had to rely either on complex and controversial correlations between the geological and palaeo-environmental sequences recorded in individual sites^{1,5}, or on equally contro-versial correlations between the character of the archaeological material recovered from the sites⁶. But thermoluminescence dating of burnt flint artefacts promises to put the dating of Mousterian sites on to a secure scientific footing.

No dating method is perfect and thermoluminescence dating of burnt flints depends on a rather complex series of calculations — and in some cases assumptions — involving not only the measurement of the thermoluminescence activity of the samples but also the environmental history of the sites and levels dated.

Fortunately there are several internal cross checks on the dates obtained for the Le Moustier sequence. The results of the thermoluminescence dating can be compared directly with the stratigraphic

sequence samples, and the dates obtained for the uppermost part of the sequence (containing an early Upper Palaeolithic industry) can be compared with the known age of these levels as documented by radiocarbon dating. In the latter case, thermoluminescence results turn out to be slightly older than would have been expected from radiocarbon evidence. but only marginally so, when allowance is made for the relatively large standard deviations attached to the thermoluminescence measurements. The consistency and internal coherence of the dates obtained for the different levels pro-vides strong corroborative evidence for the absolute chronology proposed for the Le Moustier sequence as a whole.

The present chronological structure of the French Mousterian hinges almost entirely on the correlation between the geological and archaeological successions in two key sites — Le Moustier on the one hand, and Combe Grenal (a major rockshelter site in the Dordogne valley) on the other. Previous interpretations of the geological evidence have assumed that the sequences in both sites span broadly the same range of time, and provide essentially parallel records of occupation throughout at least the greater part of the Mousterian sequence (that is, the 'Wurm I' and Wurm II' climatic phases of the current literature)³⁻⁵. Since the archaeological material recovered from the two sites is strikingly different, this interpretation carries with it the important implication that distinct industrial variants of the Mousterian were manufactured synchronously in southwestern France throughout most if not all the Mousterian period^{3,5}.

The new thermoluminescence dating of the Le Moustier sequence' argues against this intrepretation in several ways. In the first place, the earlier geological studies of Laville had postulated a substantial depositional hiatus within the uppermost part of the Le Moustier sequence (between the final Mousterian and earliest Upper Palaeolithic levels)⁴⁵ which is now seen to be untenable. More significantly, the new thermoluminescence dates show that the entire sequence of dated levels at Le Moustier (layers G to K) spans a period of only about 15,000 years, which is in sharp conflict with the earlier suggestion that these levels span a period of at least 30-35.000 years^{5.8}. Clearly, the present geological interpretations of the Le Moustier sequence will need to be substantially revised.

The long sequence of Mousterian levels recorded in the site of Combe Grenal^{9,10}, on the other hand, demonstrably spans a very much longer period. The basal levels of the sequence can be reliably attributed on both geological and archaeological grounds to the final part of the penultimate ('Riss') glaciation, while the overlying levels reveal a detailed pattern of climatic fluctuations which parallels almost exactly that recorded for the earliest stages of the last glaciation in recent studies of deep-sea cores (that is, stages 5 and 4 of the ocean-core sequence; see Fig. 1) 8.9.11-13. The geological evidence is reinforced by the archaeological record, which shows that classic 'Mousterian of Acheulian Tradition' industries - of the kind which occupy the greater part of the archaeological sequence at Le Moustier — occur only in the uppermost

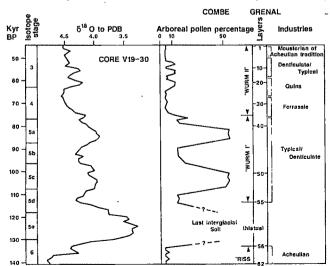

Fig. 1 Suggested correlation between the climatic sequence at Combe Grenal and the sequence of oxygen isotope stages recorded in deep-sea core V1930 (from refs 8, 9, 13 and N. J. Shackleton, personal communication). For details of archaeological sequences, see Fig.2.

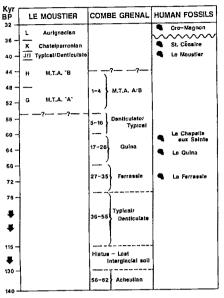

Fig. 2 Correlation between the archaeological sequences at Le Moustier and Combe Grenal implied by the new thermoluminescence dates for Le Moustier. The inferred chronological distribution of the principal Neanderthal remains from south-west France is shown in the right hand column (from refs 5, 10, 14, 15, 17). The sequence of Ferrassie and Quina Mousterian horizons at Combe Grenal is interrupted by a single level of 'Denticulate' Mousterian in layer 20, and three levels of either 'Typical' or 'attenuated Ferrassie' industries in layers 28-30; see ref. 17). M.T.A.; Mousterian of Acheulian Tradition.

occupation levels at Combe Grenal (see Fig. 2). The geological, archaeological and thermoluminescence evidence now converge in suggesting that the two sequences at Le Moustier and Combe Grenal represent essentially successive episodes in the total sequence of Mousterian occupation in south-west France, and together provide a largely complete record of human occupation in the area over a period of at least 70–80,000 years (Fig. 2).

This new chronology has radical implications for almost all aspects of our current understanding of the Mousterian period. In the first place it is now clear that any attempt to force the total pattern of climatic fluctuation during the earlier part of the last glaciation into a simple, two-fold scheme (that is, the 'Wurm I' and 'Wurm II' episodes referred to above) must be seen as a serious oversimplification of a much longer and more complex climatic succession. This in turn has direct implications for the interpretation of the archaeological record. Now that the archaeological sequences at Le Moustier and Combe Grenal can be seen to be successive rather than parallel, there can no longer be any objection to the hypothesis of a basic chronological sequence within three of the major industrial variants of the Mousterian within south-west France (that is, Ferrassie, followed by Quina, followed by Mousterian of Acheulian

Adrian Edmund Gill (1937–1986)

ADRIAN GILL, who died in hospital on 19 April after a sudden illness, will be remembered for his insight, and the almost uncanny ability he possessed to ask apparently very simple questions about ocean and atmosphere.

During the 1970s Gill - who took his doctorate under G.K. Batchelor at the University of Cambridge - began work on a seminal textbook (Atmosphere-Ocean Dynamics, published in 1982). The wide reading of both current and historical research that this involved led to the publication of many of the elegantly simple papers for which he will be remembered. His subjects included stability theory, thermal convection, internal and edge waves, and interactions between atmosphere and ocean. The lucidity of his book encapsulated his thinking for the current generation of students and researchers, and rapidly became a best-seller.

Simplicity was the key to the man and his thinking: Gill was a superb mathematician, yet one whose ability was seldom demonstrated, as this would confuse the message that he was anxious to get across not only to his theoretical colleagues but also to seagoing observationalists world-

wide. He was perpetually enthusiastic about discovering more of the physical world in which he lived. Those in Cambridge during his time there will recall the stub of pencil which lived in his jacket and which would always be in evidence at tea-time when some fluid dynamical problem would be hotly debated by those around him; or the essay on anomalous tidal flows in Greece that resulted from a family holiday in that country.

Gill travelled widely in the cause of science, and served on innumerable international working groups and committees. His concern with the world climate led to his becoming a founder member of the Committee for Climate Change and the Ocean, and to the conviction in the last years of his life that a model which coupled the global atmospheric circulation to the tropical ocean was the minimum necessary to understand short-term climatic variations such as El Niño. At the time of his death he was serving as the chairman of the Tropical Ocean-Global Atmosphere programme, one of the main components of the World Climate Research Programme, and had just been elected to the Roval Society. Peter D. Killworth

Combe Grenal had already suggested (see Fig. 2)^{3.5.6}. The same archaeological sequence is repeated in at least twelve other sites in the same region⁶.

Probably the most significant implications of the new dating however, are for the relative and absolute chronology of the various Neanderthal remains recovered from sites in south-west France. The famous Neanderthal skeleton from Le Moustier itself is known to have come from the uppermost part of the Mousterian sequence14 and therefore dated at about 40-45,000 years BP. By contrast, most of the other well-preserved Neanderthal finds are associated with archaeological material which is quite different from that recorded anywhere within the Le Moustier sequence but which compares closely with that recorded in the sequence of Ferrassie and Quina Mousterian levels at Combe Grenal 14.15. It would now appear that all of these finds including the famous 'classic' Neanderthal skeletons from La Ferrassie, La Quina and La Chapelle aux Saints - most probably date from the period of extremely harsh, glacial conditions represented by stage 4 of the ocean core sequence. If so, these finds must be dated at about 60-75,000 years BP. This is at least 15,000 years earlier than the Le Moustier skeleton, and probably 30,000 years earlier than the oldest finds of Homo sapiens sapiens forms from Cro Magnon and elsewhere (see Fig. 2).

followed by Mousterian of Acheulian | Exactly what implications this dating Tradition) — as the sequence recorded at | may have for current views on the re-

lationships between the various Neanderthal finds and their ultimate relationships with the Cro Magnon forms remains to be seen. It is already clear, however, that our whole perception of the chronology of human developments during the earlier part of the last glaciation is beginning to change and it may well be that further application of absolute dating techniques will reveal further surprises.

Speciation and our own species

SIR-It is dangerous to build a methodological artefact into dogma. Students of the modern biota are constrained to study those phenomena which are amenable to their methods. Allopatric speciation and other processes of phyletic branching can be studied using modern organisms. Speciation without branching (phyletic speciation) perhaps cannot, so it is sometimes denied1

There is some positive evidence that the transformation of Homo erectus into Homo sapiens was both more or less gradual² and occurred in different parts of the world¹⁵. The latter conclusion has been, and remains, especially common to students of East Asian and Australasian fossils. This evidence cannot simply be ignored with impunity. The phenomenon has been proposed for some other mammals also (refs 6-8 and M. Freudenthal, personal communication).

As discussed in more detail elsewhere 4.9. geographically extended phyletic speciation is a single process, not a matter of independent origin in different places in the manner of some polyploid species. The frequency of occurrence of such phyletic speciation remains controversial, but the mechanism itself consists entirely of a combination of generally accepted processes. These are, first, temporal continuity of regionally adaptive features; second, persisting gene flow from region to region; third, a single potential origin for each generally adaptive feature; and fourth, the spread of generally adaptive features by dispersal and natural selection within pre-existing regional populations elsewhere. The possibility of more than one place of partial or even complete origin is plausible for polygenic characters but it is unnecessary because of development or genetic interactions. 'Hitchhiking' and the like can partly homogenize neutral alleles and other DNA geographically. There is no more reproductive isolation at any one time than within normal species today. The above process is called speciation because it creates an entity which is adaptively (and in other respects) as distinct from its ancestor as are the species we see around us from their close contemporaneous relatives. Such differences are how paleontologists recognize allochronic species. If a later population could travel in time back to an earlier one, it might find itself reproductively isolated, but since this is both untestable and without causal effect, it is irrelevant to the pheromone. There is no implication as to how rapidly phyletic speciation may occur.

But one should not ignore the molecular evidence either, which points to differences of frequencies of variants among populations and even some qualitative

differences. These are used to construct distance matrices and phylogenetic trees, not all of which agree" even apart from the usual and (at this scale) unjustified11-13 assumption of equality of rates of change. However, in the absence of locally temporal calibration (with associated error of estimate), we really have no idea when the branchings occurred. Perhaps they really are different for different genetic elements; under selection, genomes need not disperse even approximately together. They may have occurred before the origin of H. sapiens14, in part during it, afterwards, or all three.

The suggestion 1,15 of a bottleneck in population size will be more convincing if enough genetic elements unrelated both functionally and chromosomally can be found to provide positive evidence. A bottleneck is now merely a plausible alternative; processes like meiotic drive and individual selection can mimic its results in particular cases, and different genetic elements now suggest different scenarios.

The origins of chloroplasts in eukaryotes

SIR—While I agree with most of A.E. Walsby's News and Views comment on the significance of the discovery by Burger-Wiersma et al.2 of a filamentous prochlorophyte, I must take issue with his statement that the pairing or stacking of thylakoids (chlorophyll-bearing membranes) ". . . may be a quasi-mechanical consequence of the presence of chlorophyll b and the absence of phycobilisome structures . . . " and "may not therefore be of any phylogenetic significance". This neglects a fundamental difference in the organization of photosynthesis between cyanobacteria (and eukaryotic red algae) on one hand and prochlorophytes and green eukaryotes on the other.

In cyanobacteria the thylakoid membranes are laterally homogenous; both photosystem II (which seems to be specifically associated with the phycobilisomes) and photosystem I are distributed across the whole membrane. In green eukaryotes there is a segregation of function; photosystem II is largely or entirely concentrated in appressed membrane regions, while photosystem I is predominantly located in single membranes. Freezefracture electron microscopy shows that Prochloron thylakoids are laterally heterogeneous, with a very similar pattern of intramembrane protein particles to that seen in green algae and higher plants34. There is no a priori reason why either the presence of chlorophyll b or the absence of phycobilisomes would lead to this segregation and membrane specialization; the phylogenetic significance lies in the fact that Prochloron both has the same chlorophylls as higher plants and organizes its photosynthesis in the same way. It is conceivable that chlorophyll b could have arisen more than once, but hard to imagine that each time it would have been accompanied by the same major restructuring of the photosystem organization in the membrane.

Prochloron resembles the green chloroplast in another feature, the dispersed arrangement of its DNA5; cyanobacteria almost always have their DNA in a central nucleoid⁶. Burger-Wiersma et al.² report that their organism has a central nucleoid like that of cvanobacteria and unlike other prochlorophytes. They do not mention whether or not the thylakoids are stacked, and their published micrographs do not establish this clearly. Further electron microscopy to settle this point and freezefracture studies to establish whether or not the membranes are laterally heterogeneous are the next steps towards understanding the position occupied by Prochloron in the evolution of photosynthesis.

Neurophilosophy: Toward a Unified Science of the Mind-Brain. By Patricia Smith Churchland. MIT Press: 1986. Pp.546. \$27.50, £27.50.

THE scholarly reading population divides naturally into two types. There are absorbers, people who like to be informed and who delight in the lucid presentation of unfamiliar ideas, facts and theories. Arguers, by contrast, like to fill the margins of their best-loved books with questions and comments (usually prefaced by "Yes but ...") and they prize ingenious defences of controversial theses. Patricia Churchland's new book should appeal to readers of both types.

Neurophilosophy offers an illuminating survey of contemporary neuroscience, and a review of recent developments in the philosophy of science and the philosophy of mind, which lead Churchland to a distinctive philosophical position and to a series of suggestions about how scientists and philosophers together might develop large explanatory theories of brain functioning. A leading theme of the entire book is that, in Quine's famous phrase, "there is no first philosophy". Philosophical reflection about the nature and function of minds must be informed and may be transformed - by the findings of the sciences. Conversely, philosophical synthesis of the ideas of various disciplines can prove profitable to the working scientist, to the neuroscientist as well as the psychologist, by removing conceptual blinkers and opening up new vistas for research. Churchland's philosophical naturalism may be anathema to those whose livelihood depends on keeping

"Churchland writes with the authority of an insider; one who has spent nearly a decade not only in polite conversation with neuroscientists but also with her hands in the brain."

philosophy pure, but it harmonizes beautifully with the efforts of other contemporary philosophers who have begun (or continued) a dialogue with one or another of the sciences. Moreover, *Neurophilosophy* provides an admirable illustration of how fruitful the exchange may be.

The first 235 pages present the main achievements of neuroscience past and present. Churchland writes with the authority of an insider, one who has spent nearly a decade not only in polite conversation with neuroscientists but also with her hands in the brain. She also understands clearly the predicament of the out-

sider, the curious absorber who can't tell the hypothalamus from the hippocampus. The result is a brilliant piece of exposition that should be read by anyone who is interested in what we currently know of the brain and its workings but who does not have the time to invest in a degree course in neuroscience. In my own experience, attempts to explain to non-professionals the intricacies of neuroanatomy and neurophysiology typically pile detail upon detail, technical term upon technical term, until the bewildered reader is lost in the mossy fibres. Churchland's account proves entertaining instead of soporific. partly because of her lively style, partly through the telling use of illustrations, but chiefly because of her organization of the material. What might have been a catalogue of cell types, neurotransmitters and brain areas becomes an exciting travel guide, in which we are informed both about the history of the discoveries concerned and about the nature (and limitations) of methods for acquiring information about the brain.

In the second part of her book, Churchland turns her attention to the philosophy of science and the philosophy of mind. She begins with an overview of twentiethcentury philosophy of science, in which she outlines the principal themes of logical empiricism and chronicles its death (or transfiguration?) under the impact of the ideas of Kuhn and Feyerabend. Her discussion sets the stage for a more intensive examination of the concept of "intertheoretic reduction". Churchland provides a model of reduction according to which theories are viewed as sets of sentences and reduction consists in the deduction of analogues of the statements of one theory (the reduced theory) from the principles of the other (the reducing theory).

The concept of reduction is important to Churchland because she sees the issue of the reducibility of psychology to neuroscience as the question in the philosophy of mind. Furthermore, to anticipate a little, finding an appropriate answer to this question and integrating it with our current neuroscientific knowledge might produce, as Churchland contends in the final chapter of her book, both improvements within neuroscience and a transformation of philosophy. The fundamental issue is approached carefully. After a penetrating discussion of varieties of mind-brain dualism - which will, I hope, diminish the fascination that some neuroscientists find in these hopeless doctrines — Churchland focuses on what she sees as the most sophisticated antireductionist position, the thesis that psychological states are functional states (that is, states that occupy a particular functional role in the life of an organism) which have extremely heterogeneous neurological realizations. Her critique of this position is integral to her development of her own views about psycho-physical reduction.

The kernel of Churchland's intricate and wide-ranging argument runs as follows. We should not expect neat reductions that provide simple and uniform identifications of the entities and properties discussed by the reduced theory using language from the reducing theory, and that derive "corrected versions" of the principles of the reduced theory which introduce only minor corrections. For such neat reductions are not to be found among the philosopher's paradigm cases from physics, let alone in the example, which Churchland takes to be more pertinent, of genetics. Moreover, even if the distinctions drawn by psychology should cut

"How can we make sense of mental activities without employing the ideas of folk psychology and assuming that thought involves the manipulation of symbols?"

across the divisions of neuroscience, this does not signify that psychology will persist as an autonomous science remaining irreducible to neuroscience. Rather, we ought to expect psychology and neuroscience to coevolve, so that their categories come to mesh with one another. Although this may demand the sacrifice of some everyday psychological notions, Churchland contends that folk psychology roughly that body of lore that we bring to the understanding and prediction of the behaviour of others — is in trouble anyway, and, in this connection, she cites the recent work of Stephen Stich and Daniel Dennett. If I interpret her correctly, the argument is clinched by appeal to the unity of science. Functionalists who flaunt the irreducibility of psychology are to be hoist with their own petard. Unity of scince demands that the barriers to reduction must be removed, and psychology (or neuroscience) must amend itself to suit.

I am not convinced by this line of reasoning. One source of my resistance lies in the fact that, while she is happy to advocate conceptual reform for psychologists, and though she explicitly considers the possibility that science might lead us to modify our philosophical concepts, that possibility is not taken seriously in the present context. Perhaps Churchland is right in thinking that something like the

question of reducibility of psychology to neuroscience is the fundamental problem in the philosophy of mind. Yet the analogy I draw from the case of genetics is that the philosophical concept of reduction is inadequate to the representation of the relations among many theories (or fields) of science*. To borrow Churchland's own terminology, I think that the concept of reduction may belong to folk metascience.

A second concern about her argument derives from a different way of appealing to the unity of science. One of the leading themes of functionalism is the view that there are generalizations about psychological processes — couched in terms of representation and computation — which apply to systems that are built out of very different materials. Assuming that such generalizations cannot be integrated into neuroscience, the functionalist may reasonably protest against their sacrifice on the altar of the unity of science on the grounds that they already contribute to a unified science by linking together the study of different forms of intelligence both artificial and natural. Churchland's apparently clinching argument thus seems to presuppose a particular view of how an ideally unified science must be organized, a view on which neuroscience stands as the neighbouring discipline to psychology. Functionalists who believe in unified science should adopt a different picture of its structure, and they may accuse Churchland of extracting more from a methodological principle than it can fairly

These reservations do not detract from the achievement of the second part of Neurophilosophy. Whether or not one agrees with her, Churchland has performed a great service for philosophers, psychologists and neuroscientists through her elaboration of the major positions and her clear presentation of arguments. Equally, the long and fascinating chapter that makes up the third and final part of the book, should serve as the starting point for serious interdisciplinary discussions.

We learned in Churchland's review of neuroscience that the various branches of the field are urgently in need of theory. Attention to the philosophy of mind offered the moral that philosophical conceptions, including those that strike us as untutored common sense, may have to be "reconfigured". But what are the prospects for theories in neuroscience? And how can we make sense of mental activities without employing the ideas of folk psychology and assuming that thought involves the manipulation of symbols? Churchland's final chapter outlines some

answers to these questions. She gives a lucid account of some recent research: the tensor network theory of Pellionisz and Llinas (and a related proposal by Paul Churchland), the parallel models of computation developed by Rumelhart and McClelland, and a hypothesis of Crick's about the neurobiology of attention. In each case, there appears to be an exciting symbiosis between naturalistic philosophy and theoretical neuroscience, with the liberation from conceptual chains leading to new prospects for developing theory.

Tensor network theory receives the most extended treatment. The core of the Pellionisz-Llinas proposal is that synaptic connections in the cerebellum can be viewed as an array for performing matrix multiplication. So, to simplify enormously, sensorimotor coordination might be achieved by means of the registering of information on a sensory map in the brain, the "computation" in the cerebellum of an appropriate vector in a motor map, and, as the result of the stimulation of the right region of the motor map, the activation of the proper muscles. The proposal is especially stimulating because the 'computation" does not involve manipulation of symbols. Algebra gives way to geometry. Churchland offers a succinct summary:

What is needed is a way to conceive of what nonsentential representing might be, and the tensor network theory provides that much, even if, in the end, it turns out not to be right [p.452].

Functionalists will be quick to protest that managing without symbol manipulation in the case of sensorimotor coordination is one thing, doing the same in the case of language learning quite another. Neuroscience can cope with the more mundane operations of the brain, but the higher cognitive functions require a more abstract treatment. Taken as a cautionary note, this is perfectly correct, but the point should not be overinterpreted. The work Churchland describes is extremely tantalizing, for neuroscience, for psychology and for philosophy. We do well to recognize exactly how far we have gone, but not to make unwarranted judgments about how far we may go.

Churchland is plainly optimistic, and her optimism may ultimately prove unjustified. But, whatever the outcome of the trends in theoretical neuroscience that she favours, the value of her book is independent of its more speculative claims and its more controversial arguments. While reading it, I was reminded of the comments of numerous friends, who mourn the good old days --- days when there were far fewer academic books, when books were read by several generations of graduate students, when the brief bright ideas emerged on journal pages but not in the more enduring medium of hard covers. Such people should be happy with Churchland, for she has given them a book of the old-fashioned sort, one that deserves to be read and pondered by philosophers, psychologists and neuroscientists for a good long time.

Philip Kitcher is Director of the Minnesota Center for the Philosophy of Science, 315 Ford Hall, 224 Church Street SE, Minneapolis, Minnesota 55455, USA. His most recent book is Vaulting Ambition: Sociobiology and the Quest for Human Nature (MIT Press, 1985).

Revival in optics

O.S. Heavens

Optical Interferometry. By P. Hariharan. *Academic: 1986. Pp.303.* \$58, £49.50.

OPTICS — until recently perhaps regarded as satisfactorily completed and with little more to be expected — has experienced a resurgence of interest since the arrival of the laser, a tool of almost infinite sharpness compared with the light sources previously available. The laser has not only made many traditional optical techniques more convenient, but has made possible methods such as holography which were hitherto practically impossible.

An account of optical interferometry can thus be expected to contain some new excitements to complement the more traditional material. In this sense, Hariharan's book is no disappointment: holography, holographic interferometry and speckle inteferometry — all post-laser subjects — are well covered in a mainly

readable fashion. There are some grumbles. The pedagogue tires of explaining to students why the term "phase of a photon" is completely meaningless, but here it is again. There is, too, an uneven quality to the book in that rather basic algebra is spelled out at length while a knowledge of Jones matrices is assumed. Some carelessness in checking the matching of symbols in text and figures has introduced glitches in reading, and many of the line diagrams could have been made clearer by the use of shading.

One instinctively draws a comparison between this book and the classic work of Steel, Interferometry, of which a new edition appeared in 1983 and which is now available in paperback (Cambridge, £12.95, \$24.95). They have much in common, since Steel's updating of the earlier (1967) book was thorough. The better diagrams of Steel's version and freedom from some of the blemishes referred to above, will probably mean that its sales will not suffer.

O.S. Heavens is Profeassor of Physics, University of York, York YO1 5DD, UK.

How does the brain do it?

Stuart Sutherland

Visual Cognition. Edited by Steven Pinker. MIT Press: 1986. Pp.270. Pbk \$17.50, £17.50.

Many years ago, I put forward the following problem. A cross and a circle, horizontally aligned, are flashed onto the retina; regardless of the shapes' absolute positions, the subject has to determine which is on the left. As visual tasks go, it could hardly be simpler: the problem is that we have no idea how the brain does it. A scan from left to right (or vice versa) seems improbable. If, on the other hand, the coordinates of each shape are carried forward, how is this done and how is the comparison between the coordinates made in neural terms?

In the most original and important article in *Visual Cognition*, Shimon Ullman points to a series of similar problems. He asks what mechanism could trace out a closed curve to decide that it is closed and to determine which points lie inside and which outside it. The problem is a more precise version of the figure-ground effect, so beloved by the Gestaltists. Although the question can be stated more rigorously than in their day, we are no nearer a solution, at least in terms of brain mechanisms, for there is no difficulty in writing computer programs to carry out this task.

At the other extreme of vision are complicated problems which still defy computers, but which are solved by the brain by means that remain obscure. Perhaps the most difficult is that of visual recognition. Steven Pinker gives a judicious review of the subject, noting the many difficulties that beset current theories. We have of course moved on: nowadays Gestalt theorizing looks hopelessly vague, and the idea that recognition could be achieved by templates or by feature matching, which was being put forward in all seriousness only 20 years ago, now looks extremely naive. Some of the more recent ideas will probably survive, for example that, for the purposes of recognition, the brain builds an abstract and hierarchical structural description of an object. However, the exact nature of such descriptions, the methods by which they are derived from the retinal image, and how or indeed whether the same description is formed of an object regardless of viewpoint remain entirely open questions.

Half of the papers collected by Pinker are devoted to visual imagery and the ways in which people manipulate it, a subject on which there has recently been much research. There are a limited num-

ber of transformations that can be applied to the image of an object — it can, for example, be made to change size, to rotate or to change position. In all such changes, the imaged object passes through all intermediate points. One cannot suddenly replace an image of an upright letter with that of the same letter tilted through 90°. Steven Kosslyn has constructed an ingenious computer model which incorporates the processes required to manipulate imagery in the way people do. He describes his model and the results of submitting it to a series of tests, in which he uses consistent differences in people's ability to perform the different operations to demonstrate that they really are used by

Such questions as whether the tail of a horse ends above or below its kilees can only be answered by using imagery. But if for the purpose of recognition we construct structural descriptions, it is puzzling that the answer cannot be read off directly from them. Perhaps this relationship is only implicit in the description, making it necessary to generate an image from the structural description and derive the answer from that.

The present volume, originally a special issue of the journal *Cognition*, is useful in so far as it delineates the state of the art in a few branches of vision. It makes it clear that we have advanced mainly by discovering and making precise an increasing number of problems, and that theorizing is more rigorous than ever before. But although the secret of how the brain subserves vision has for some time appeared to be just around the corner, it still remains elusive. How, for instance, does my brain calculate that my typewriter lies to the left of my gin bottle?

Morphological eye

Malcolm Irving

Skeletal Muscle. Handbook of Microscopic Anatomy, Vol.2, Part 6. By Henning Schmalbruch. Springer-Verlag: 1985. Pp. 440. DM 580.

THE PREVIOUS edition of this handbook was published in 1956, a time of revolution in muscle research. The idea that contraction involved the relative sliding of two sets of filaments was new, and the first clear electron micrographs of the side-by-side array of interdigitating filaments were still to be published. In the 30 years since then electron microscopes seem to have been focused on every structural feature in muscle, so that we now have a fairly complete picture of its ultrastructure, at

least down to a resolution of about 10nm. Parallel progress with other techniques has in many cases helped to reveal the functional significance of the structural specializations.

This new edition is therefore long overdue and, in attempting to review progress since the last one. Schmalbruch was confronted with an embarrassment of riches. He has reduced his subject to manageable proportions by concentrating on one approach to the study of muscle, which he describes as "muscle seen through the eves of a morphologist". This allows him to treat a wide range of biologically interesting phenomena from a unified viewpoint. The morphological aspects of neuromuscular transmission, contractile proteins and the mechanism of force generation, internal membranes and the regulation of contraction, metabolism and fibre types, development and regeneration are all dealt with in some depth. A wide range of other features, for example connective tissue, vascularization and the organization of motor units, are described more briefly. The emphasis is on mammalian muscle (including a section on non-skeletal striated types, but excluding cardiac muscle), though results from studies on other animals are discussed where they serve as useful experimental models. Pathological states are mentioned in passing but not treated systematically.

Schmalbruch has painstakingly organized and cross-referenced his material. which is also beautifully illustrated by over 200 micrographs and backed up by about 2,000 references. He does not hesitate to pepper the text with quantitative detail where it is available (thus we learn that a 10cm cell from a human biceps contains 3.000 nuclei), or to resort to descriptions of "amorphous densities" or "ill-defined periodic structures" where it is not. Technical issues, such as possible problems in the use of a particular fixative, are discussed where they might affect the interpretation of the literature. The rather empirical "morphologist's eye" approach adopted for most of the book often leaves the reader to draw his or her own conclusions from the data; sometimes, though, as in the section on myogenesis. Schmalbruch allows himself to discuss alternative hypotheses, giving freer rein to the morphologist's brain.

This book is more than an atlas of muscle structure, but less than a complete account of the structural basis of muscle function, and it will probably be of more use to the research worker than to the undergraduate. It should remain a useful reference volume for a long period—it not quite until the publication of the next edition, which at the present rate should appear sometime after the year 2010.

Neolithic battles

William H. McNeill

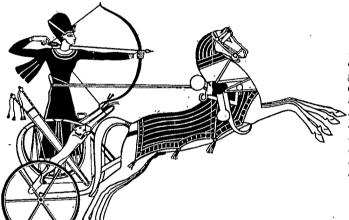

The Origins of War: From the Stone Age to Alexander the Great. By Arther Ferrill. Thames & Hudson: 1985. Pp.240. Hbk £12.50, \$19.95; pbk £5.95, \$10.95.

ARTHER Ferrill is a professor of ancient history at the University of Washington, Seattle, and in this book he advances two general propositions that are likely to surprise most readers, as they did me.

First, he describes a Neolithic "burst of organized warfare" in the Near East which, he argues, was "as important for the area as Alexander's conquest of Persia in the fourth century BC or the march of Islam in the seventh century AD" (pp. 27–28). New weaponry was part of this change: the bow, the sling, the dagger and the mace all start to appear in the archaeo-

the phalanx, which supplanted that form of warfare among the Greeks in the seventh century, were rudimentary indeed. Only in the second half of the fourth century BC, when Greek and Macedonian captains had learned the art of war from prolonged service as allies and mercenaries of the Persians, did Philip and Alexander successfully unite Greek-style heavy infantry with Persian combined arms - skirmishers, light and heavy cavalry, siege trains, a supply system and, not least, generalship capable of using all arms efficiently in mutual support. With that development. Ferrill claims, the art of war reached a plateau where it remained until after 1815. He supports the claim by refighting the battle of Waterloo with Alexander and his army in Napoleon's place, and concludes that the ancients might well have won, assuming some prior acclimatization to the noise of gunfire (pp.220-222).

Obviously, Ferrill's claim of Persian

Ramesses II in his war chariot at the Battle of Kadesh in 1285 BC: his lighter chariots and strategy gave him a tactical advantage against the Hittites. Ramesses' strategy and tactics showed a degree of military sophistication that was not seen in many later historical periods.

logical record between 12000 and 8000 BC. Regular military formations (column and line) made the use of such weapons more effective, and elaborate fortifications had to be built to protect against organized attack—all before settled agriculture had become widespread. Indeed, Ferrill suggests that fixed residence, dictated by the need for protective walls, may have led to the development of fixed agriculture (p.29), without, however, pressing the point as to which came first.

Ferrill's second proposition is that classical Greek warfare was backward and technically deficient compared with the military techniques and command system of the Persian empire. That empire, heir to Bronze Age empires and to the even more impressive Assyrian techniques of waging war, added a navy to combinedarms warfare on land, and could in addition support both branches with an adequate logistical system. By comparison, the Greek style of hurly-burly duelling between aristocratic horsemen (who Ferrill says, dismounted to fight in the eighth century: hence Homer's chariot tactics!) and the unsupported charge of

superiority in the fifth and fourth centuries requires him to explain away Greek victories on the plain of Marathon and at Plataea. His schematized accounts of the battles leave aside all the innumerable contested issues as to what actually happened. If Persian combined arms were so superior, why did they not prevail on these occasions? Ferrill's brief battle narratives simply do not show "that the Persians were defeated by their own mistakes", although he declares that this view "must surely be correct" (p.122).

Throughout, the author uses the style of an essayist, and simply asserts what must often be guesswork. He reaches for novelty of interpretation, and perhaps overreaches himself. But as long as one understands what treacherous ground he traverses, and how controversial most of his assertions are, the book makes good reading; and I, for one, was persuaded that the Neolithic "military revolution" in the Near East was as real and important as Ferrill says it was.

William H. McNeill is a Professor in the Department of History, University of Chicago, 5801 S. Ellis Avenue, Chicago, Illinois 60637, USA.

Good and the bad

John Crothers

The Encyclopaedia of Reptiles and Amphibians. Edited by Tim Halliday and Kraig Adler. The Encyclopaedia of Insects. Edited by Christopher O'Toole. George Allen & Unwin/Facts on File:1986. Both: Pp.152.£15, \$22.50.

THESE are the fifth and sixth volumes in the deservedly successful Unwin Animal Library. Previous titles have dealt with mammals (two volumes), birds and underwater life. The features uniting all these works are a systematic format, authoritative, concise text, and superb illustrations; all are beautifully produced and are a pleasure to read.

The Encyclopaedia of Reptiles and Amphibians must be the best book on herpetology currently available to the general reader - and there can be few professional zoologists working in related fields who will not welcome it onto their shelves. The extraordinary collection of colour photographs is augmented with quite excellent paintings. But, unlike many beautiful books, the text would stand on its own. It is arranged ordinally, with a small box at the beginning of each section describing the main features of the order (or sub-order) concerned — the number of species, their distribution, habitats, size, colour, reproduction and longevity. There are also separate sections on parthenogenesis, shedding of lizard tails and so on.

I was initially surprised to find no mention—in the systematic part—of the influence of temperature on sex determination in crocodilians, but the topic is discussed earlier in the general introduction to reptiles. Unlike *The Encyclopaedia of Mammals*, this volume does not include an appendix listing species, genera and families, and giving both the scientific and colloquial names. But that is just about my only criticism.

By comparison, the volume on insects is disappointing. The title is misleading, as the work seeks to cover most of the terrestrial arthropods, and for some reason it has been decided that all these invertebrates only justify 143 pages of text (the same as amphibians and reptiles), against 895 for the mammals. The 9,000 species of reptiles and amphibians have an entire book to themselves but the 11,500 species of millipedes, centipedes and their allies are covered in just four pages of this one. Even the 300,000 known species of Coleoptera (beetles) are given only twelve. The result, inevitably, is a very much more superficial account.

John Crothers is Warden of The Leonard Wills Field Centre, Nettlecombe Court, Williton, Taunton, Somerset TA44HT, UK.

Kelvin on an old, celebrated hypothesis

from Edward Harrison

Lord Kelvin in 1901 tested an "old and celebrated hypothesis" that if we could see far enough into space the whole sky would be occupied with stellar disks all of perhaps the same brightness as the Sun. Kelvin was the first to solve quantitatively and correctly the riddle of a dark night sky, a riddle that had been previously solved qualitatively by Edgar Allan Poe, and is now known as Olbers' paradox.

IN a paper¹ published in 1901, Lord Kelvin discussed various astronomical topics, such as the size and mass of the Galaxy, the velocities of stars, and the dark night-sky riddle. Kelvin's treatment of the riddle of darkness at night is of considerable scientific and historical interest; for the first time in the context of a static universe he solved the riddle quantitatively and correctly. This paper was reproduced in 1904 as the revised Lecture XVI in the Baltimore Lectures2. The omission of this paper from Kelvin's Mathematical and Physical Papers3 and from the complete bibliography of his works in Silvanus Thompson's Life of William Thomson4 may account for its neglect in numerous subsequent discussions of the so-called Olbers' paradox⁵⁻⁷.

The riddle of a dark starlit sky can be traced back to Thomas Digges in 1576 and Johannes Kepler in 1610⁸. The modern expression 'Olbers' paradox' gained popularity in ignorance of these contributions, and of those made by Otto von Guericke⁹ in 1672, Edmund Halley¹⁰ in 1721, Jean-Philippe Loys de Chéseaux¹¹ in 1744, and many others, all of which preceded the work by Wilhelm Olbers in 1823¹².

The riddle is easily stated in the form proposed by Olbers. Plausibly, space is unbounded and stars are scattered throughout space; a line of sight extended in any direction ultimately intercepts the surface of a star. Every point of the sky must blaze with starlight with no dark gaps between the stars. If most stars are like the Sun, the sky at every point must be as bright as the Sun's disk. The sky subtends a solid angle 180,000 times that of the Sun, so the starlit sky should be 180,000 times brighter than the Sun. But the sky at night is dark—hence the riddle.

Kelvin's analysis

The following parallels the analysis given by Kelvin. We assume for computational convenience that all stars are Sun-like, of radius a, and uniformly distributed. Let n be their number per unit volume. Then the number in a shell of radius q and thickness dq is $4\pi nq^2dq$. This number multiplied by $a^2/4q^2$ represents the fraction of the whole sky covered by stars viewed by an observer at the centre. To include geometric overlap of stellar disks, neglected by Kelvin, we

multiply by $\exp(-q/\lambda)$, where $\lambda = (\pi na^2)^{-1}$ is the mean free path of a light ray. Hence the fraction of the sky covered by stars in the shell is $\exp(-q/\lambda) dq/\lambda$. By integrating from q = 0 to q = r we obtain

$$\alpha = 1 - e^{-r/\lambda} \tag{1}$$

where α denotes the fraction of the sky covered by stellar disks out to radius r. In a distribution of stars of infinite extent the entire sky is covered $(\alpha = 1)$ and the average distance seen from any position is the background limit λ . We arrive at Kelvin's result (his equation (10)) when the radius r of the distribution of stars is small compared with the background limit, so that

$$\alpha \simeq \frac{r}{\lambda} = \frac{3N}{4} \left(\frac{a}{r}\right)^2 \tag{2}$$

where $N = 4\pi r^3/3$ is the total number of stars. This treatment by Kelvin elucidates that previously given by Halley, Chéseaux and Olbers.

Let each star have luminosity L. The contribution to the radiation density u at the centre from the stars in a shell is $(nL/c)e^{-q/\lambda}dq$, where c is the speed of light. By integrating as before we find

$$u = u^*(1 - e^{-r/\lambda})$$
 (3)

where $u^* = L/\pi a^2 c$ is the radiation density at the surface of a star¹³. Hence $u = u^*$ in any distribution of stars extending much beyond the background limit.

From equations (1) and (3) we obtain

$$\alpha = u/u^* \tag{4}$$

thus demonstrating the truth of Kelvin's remark that " α is the ratio of the apparent brightness of our star-lit sky to the brightness of our Sun's disc." In many recent discussions of the riddle this significant relation has received scant recognition.

Solutions

With his model of the Galaxy, consisting of a sphere of radius 10^3 pc (1 pc = 3.26 light-yr) containing 10^9 Sun-like stars, Kelvin found $\alpha = 4 \times 10^{-13}$, and said, "This exceedingly small ratio will help us to test an old and celebrated hypothesis that if we could see far enough into space the whole sky would be seen occupied with discs of stars all of perhaps the same

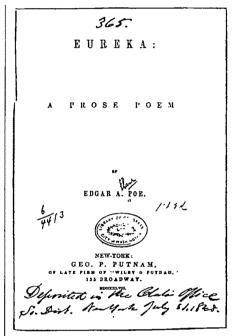

Fig. 1 The title page of Edgar Allan Poe's Eureka, published in June 1848, dedicated to Alexander von Humboldt, and based on a two-hour lecture, "The cosmogony of the universe". delivered at the Society Library, New York, in February 1848 while the Rev. Dr John Pringle Nichol, regius professor of astronomy at the University of Glasgow, was also lecturing in New York.

brightness as our own Sun."

We require, said Kelvin, a "great sphere" of stars, of radius λ ($\approx 10^{14}$ pc), to cover the sky with stellar disks. But starlight travelling from the outlying stars of such a great sphere takes 3×10^{14} yr to reach us. Using the theory that stars derive their energy by gravitational contraction, he said, we know that 108 yr is an upper limit for a stellar luminous lifetime. "Hence, if all the stars through our vast sphere commenced shining at the same time...at no one instant would light be reaching the Earth from more than an excessively small proportion of all the stars." In this remarkable argument Kelvin showed that the transit time of light from the background limit greatly exceeds the luminous lifetime of stars. If all stars began to shine at the same instant, we see light only from stars in the foreground, not from those in the distant background.

Relativity theory had yet to stress the

universality of $E = mc^2$, which provides a true maximum luminous lifetime $M_{\odot}c^2/L_{\odot}$ of $\sim 10^{13}$ yr for the Sun. This extreme value is still less than Kelvin's limit of 3×10^{14} yr and could not have altered his conclusion. It was not evident in Kelvin's day that the universe contains insufficient energy to create a bright starlit sky¹⁴. We now know that the conversion of all mass in the universe into thermal radiation would attain at most a temperature of 20 K, much less than the Sun's surface temperature of 6,000 K.

We may re-write equation (3) in the

$$u = u^*(1 - e^{-t/\tau}) \tag{5}$$

where t = r/c is the transit time of light from stars at distance r, and $\tau = \lambda/c$ is the transit time from the background limit. When α is small,

$$\alpha = u/u^* = t/\tau \tag{6}$$

thus confirming Kelvin's conclusion that the sky is dark because the transit time τ from the background limit greatly exceeds the maximum value of t equal to the stellar luminous lifetime. Equation (5) can be derived thermodynamically by considering the radiation density in a cavity containing luminous sources; t is then the timespan during which the sources emit radiation and τ the characteristic time required to fill the cavity with radiation in equilibrium with the sources14.

Edgar Allan Poe was perhaps the first to give a correct qualitative solution to the riddle of darkness. In 1845 he wrote¹⁵,

Look down into the abysmal distances!attempt to force the gaze down the multitudinous vistas of the stars, as we sweep slowly through them thus-and thus-and thus! Even the spiritual vision, is it not at all points arrested by the continuous golden walls of the universe?-the walls of the myriads of the shining bodies that mere number has appeared to blend into unity?

Three years later, in his masterpiece Eureka¹⁵, he formulated his most radical cosmological ideas. Concerning the riddle of darkness, he said,

Were the succession of stars endless, then the background of the sky would present us an uniform luminosity, like that displayed by the Galaxy-since there could be absolutely no point, in all that background, at which would not exist a star. The only mode, therefore, in which, under such a state of affairs, we could comprehend the voids which our telescopes find in innumerable directions, would be by supposing the distance of the invisible background so immense that no ray from it has yet been able to reach us at all.

A few lines he wrote, "I myself feel impelled to the fancy-without daring to call it more—that there does exist a limitless succession of Universes, more or less similar to that of which we have cognizance." By "Universes" he meant the

Fig. 2 Title page of the Baltimore Lectures, published in 1904. Kelvin's solution of the riddle of darkness is given in Lecture XVI, pages 260-278. The solution does not appear in the original lecture notes of 1884, and was first published in 1901 in the Philsophical Magazine in a paper entitled "On ether and gravitational matter through infinite space".

Galaxy and other galaxies. The finite speed of light and the age of the starlit universe had come together in Poe's fertile mind, shedding new light on an old hypothesis.

Comments

Despite the widespread interest in Olbers' paradox in recent years, little attention has been paid to the pertinent comments in the nineteenth century by William Herschel, Olbers, Nichol, Poe, Thomas Dick, Friedrich Struve, Alexander von Humboldt, John Herschel, Richard Proctor, Hugo von Seeliger, Ellard Gore, Lord Kelvin and others^{6,9}

John Pringle Nichol, who introduced the word 'evolution' into astronomy and was regius professor of astronomy at Glasgow University from 1836 to 1859, greatly inspired both Kelvin and Poe. Kelvin acknowledged his debt when recalling his student days17,18. Much of Poe's knowledge of contemporary developments in astronomy came from Nichol's influential Views of the Architecture of the Heavens 19,20, to which he made reference in Eureka. Nichol's astronomy lectures stressed the importance of the transit time of light.

Kelvin pointed out that the supposition of uniform density is arbitrary, and "we ought in the greater sphere to assume the density much smaller than in the smaller sphere." Allowing for the reduced density of stars in the universe because of the wide separation between galaxies, the background limit of Poe's golden walls recedes to 10²³ light-yr. With a typical steller luminous lifetime of 1010 yr we see that the fractional coverage $\alpha = 10^{-13}$ departs little from Kelvin's value.

According to Kelvin the sky at night is dark because the radius of the starlit visible universe, equal to the time stars have been luminous multiplied by the speed of light, is small compared with the background limit, where the background limit is the distance to which stars must extend in order to cover the entire sky. Starlight emitted beyond the visible universe has yet to reach us. Kelvin thus solved the riddle in its original cosmological framework: a static universe of uniformly scattered, Sun-like stars. All variants of this primitive standard model seeking to solve the riddle by appeal to absorption, hierarchy, expansion or fatigued light merely achieve a state of greater darkness in a universe already dark.

Bondi⁵ resurrected the riddle within the context of the steady-state theory. Continually created stars shine unceasingly, according to this theory, and expansion maintains starlight at a constant level. Expansion is necessary (but not sufficient) for darkness, and Kelvin's solution fails in the steady-state model because of its non-conservation of energy.

More than once Kelvin said, "paradoxes have no place in science"21. He took the rationalist view that paradoxes lie in ourselves and not the external world. It is historically ironic that he was the first to solve quantitatively with utmost lucidity a riddle that later, when his work lay forgotten, became known as Olbers' paradox.

The long and the short of long-term memory—a molecular framework

Philip Goelet, Vincent F. Castellucci, Samuel Schacher & Eric R. Kandel

Howard Hughes Medical Institute, Center for Neurobiology and Behavior, Columbia University College of Physicians and Surgeons, and New York State Psychiatric Institute, New York, New York 10032, USA

A single learning event initiates several memory processes with different time courses of retention. While short term memory involves covalent modification of pre-existing proteins, the finding that long-term memory requires the expression, during learning, of additional genes, makes it possible to analyse in molecular terms the induction and retention of long-term memory.

ANIMALS acquire new information about the world through mechanisms of learning, and retain that information through mechanisms of memory. Clinical and experimental observations indicate that memory is not a unitary process but is thought to have at least two forms, each of which subserves a family of time courses: a short-term form that can last seconds, minutes and hours, and a long-term form lasting days, weeks or years¹⁻⁵. To understand the mechanisms of the major forms of memory, it will be necessary to describe, in cellular and molecular terms, the inductive mechanisms used in the acquisition of information for each form of memory and the various molecular time-keeping steps involved in retaining the resulting memories.

Studies in certain invertebrates (Aplysia, Hermissenda and Drosophila) have shown that the acquisition and retention of information for short-term memory lasting minutes to hours does not require the synthesis of new proteins. Rather, it depends on second messenger-mediated covalent modifications of previously synthesized proteins that modulate the properties of nerve cells and their synaptic connections⁶⁻¹³. Acquisition involves the activation, by neurotransmitters, of receptor-linked enzymes responsible for the synthesis of intracellular messages. These second messengers activate protein kinases that phosphorylate substrate proteins required for the plastic neuronal modifications (Fig. 1, pathway 1). Retention of these plastic changes depends on the duration of the covalent modification of the substrate proteins and the maintained activity of the enzymes responsible for second-messenger synthesis.

Covalent modifications of the sort used in short-term memory have been proposed to become self-reinforcing for certain instances of long-term memory¹⁴⁻¹⁸. However, a variety of studies now indicate that during the acquisition of information whose memory lasts more than 1 day, specific nerve cells need to express genes that are not needed for short-term memory^{5,19-21}. These studies lead us to outline a specific molecular framework for the various time courses of long-term memory. We think it likely that the same modulatory neurotransmitters that act on the cell surface to induce cytoplasmic messengers during learning are not only important for short-term memory, but also lead, through either the same or additional second-messenger systems. to the activation of at least three other overlapping memory processes, each with its own time course of retention (Fig. 1, pathways 2, 3 and 4): (i) A self-reinforcing covalent modification of proteins, encoding for memory lasting many hours. (ii) A transient activation of effector genes for memory lasting more than 1 day, where the time course of memory retention is simply determined by the half-lives of the induced messenger RNAs and proteins. (iii) The induction of a gene sequence for memory lasting weeks or months, in which early regulatory genes lead to maintained alterations in the expression of late, effector genes. Here, the molecular time-keeping step for memory retention is in the maintenance of an altered mRNA transcription or processing state, much as it is in cellular differentiation.

Time window

Whereas short-term memory does not require the synthesis of new proteins⁶, behavioural studies of learning in vertebrates suggest that memory lasting days or weeks can be disrupted by the inhibition of protein synthesis^{5,19,22,23}. Particularly important for the arguments we develop below is the finding that long-term memory is most sensitive to disruption during and immediately after training. Vertebrates experience no deficit in long-term memory if exposure to the protein synthesis inhibitor is delayed by as little as 1 h after training ^{5,19,23}.

This time window for protein synthesis has been found in both lower vertebrates and mammals, and for learning processes that range in complexity from non-associative forms, such as sensitization, to associative forms, such as classical and instrumental conditioning. Although comparable data are lacking in humans, there is the interesting and analogous clinical observation that long-term memory for an experience is particularly susceptible to disruption by convulsions or trauma during and briefly after the experience. Because these findings were based on alterations in behaviour, the studies failed to answer the question of whether this sensitivity to disruption by protein synthesis inhibitors is a systems property of motivation, motor performance or some other complex brain system, or whether it actually reflects a fundamental property of long-term information storage in specific nerve cells of the circuit responsible for the modified behaviour.

This question has now been answered in invertebrates where the neuronal circuitry underlying behaviour and learning is better understood. Studies on long-term sensitization of the gill-withdrawal reflex in Aplysia demonstrate that the elementary synaptic connection between sensory and motor neurones, which is enhanced during short-term sensitization, is also enhanced during long-term sensitization²⁴. Examination of this connection in dissociated cell culture has shown that a single application of a facilitating transmitter enhances synaptic transmission for minutes, whereas four or more repeated applications lead to long-term facilitation lasting for over 24 h (ref. 20). In contrast to short-term facilitation at this synapse, the long-term facilitation associated with the memory of long-term sensitization is blocked by both translational and transcriptional inhibitors. As in vertebrates, transient blockage of protein synthesis in Aplysia during a 2-h training period is sufficient to block the retention of long-term facilitation assayed 1 day later (refs 20, 21, and V.F.C. et al., in preparation). Similarly, inhibition of both protein and mRNA synthesis after training has little effect on long-term memory assayed 1 day later.

These findings indicate that a critical and general feature of long-term memory characteristic of many forms of learning in vertebrates and perhaps also in human beings-a narrow time window during which new proteins must be synthesizedreflects a fundamental property in the storage of information by specific neurones and their connections. As a result, the findings lead to three specific molecular conclusions: (1) that the same extracellular signal (the same neurotransmitter) that initiates short-term memory also initiates long-term memory; (2) by contrast, there are genes and proteins necessary for the cellular mechanisms underlying long-term memory that are not required for the mechanisms of short-term memory; (3) whereas proteins and mRNAs critical for short-term memory are preexisting and turn over slowly, certain proteins and mRNAs necessary for long-term memory must be either induced or, if constitutively expressed, only transiently accessible to modification.

Constitutively expressed proteins

Several models of long-term memory have considered the participation of constitutively expressed proteins which are present in an inactive form prior to learning. Acquisition, during learning, involves the activation of these proteins, perhaps by means of covalent modification. Retention of the memory relies on self-reinforcing mechanisms which outlast the turnover times of both the modifications and the proteins themselves. In one such model, Crick¹⁴ proposed that acquisition of memory is achieved during learning by a system (perhaps a cytoplasmic second-messenger system) which shifts a dimer to an active state where both subunits are modified. This active state can then be retained despite turnover of a single subunit, by an enzyme which can modify one monomer only when the other is modified.

In a more detailed model, which has now received some experimental support, Lisman¹⁷ proposed that competing activities of an autophosphorylating kinase and an associated phosphatase make up a 'bistable switch'. Learning stimulates the phosphorylation of the kinase and thereby initiates its autophosphorylation. When the rate of autophosphorylation exceeds that of dephosporylation, phosphorylation of the kinase becomes independent of the stimulus provided by learning. Support for this aspect of the model derives from studies on the Ca²⁺/calmodulin protein kinase in which intramolecular autophosphorylation permits persistent activation of the kinase in the absence of Ca²⁺ (refs 16, 18). For Lisman's model to be independent of protein turnover either autophosphorylation must be intermolecular or subunit exchange must take place. Neither of these has yet been demonstrated.

Based on studies of long-term potentiation, Lynch and Baudry¹⁵ suggested a model involving the self-reinforcing disassembly of molecular assemblies. They found that during acquisition, Ca²⁺ influx produced by learning rapidly and irreversibly increased the number of glutamate receptors in the synaptic membrane by activating calpain, a protease that degrades fodrin, a structural protein in the postsynaptic cell. This degradation is proposed to be the means whereby changes in activity in the postsynaptic cell lead to the insertion of new glutamate receptors; these, in turn, enhance Ca²⁺ entry and provide the reinforcement necessary for the maintenance of the memory.

These three models, however, do not account for the requirement of protein and mRNA synthesis during learning for memory lasting one day or more. Conceivably, constitutively expressed proteins with self-reinforcing properties could share the pharmacological sensitivity of long-term memory if these proteins and their mRNAs were either rapidly turned over or only available to modification during a brief period of their biogenesis. We think, however, that in their present form these models readily account for memory processes lasting many hours. The extracellular signals and second-messenger systems responsible for short-term memory could therefore activate a

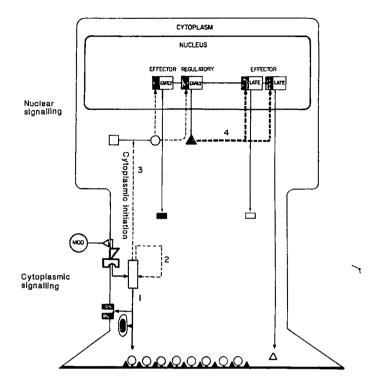

Fig. 1 Possible signalling systems used to activate memory systems with various time courses. For schematic reasons we have arbitrarily selected a presynaptic neurone at a synapse and consider how various acquisition processes could lead to the activation of retention processes with different time courses. These retention processes in turn initiate and maintain functional changes in ion channels, transmitter release mechanisms and structural changes at active zones. Similar changes in the properties and insertion of receptors are likely to occur in postsynaptic cells. In this model, a common extracellular signal, a transmitter released by modulatory neurones (MOD), acts on a presynaptic neurone to initiate separate memory processes with different durations. Short-term memory, which has a time course of minutes to hours (pathway 1), involves covalent modification of pre-existing proteins. Common components of cytoplasmic signalling [membrane receptor, transducing proteins, amplifier enzyme (adenylate cyclase, phospholipase C), cytoplasmic signal (cAMP, Ca²⁺, IT₃ triacylglycerol), protein kinase (A, B or C)] are used to modify target proteins (gated K⁺ channels, Ca²⁺ handling system, transmitter release mechanism). The duration of these modifications determines the retention of memory. For intermediate memory, this short-term memory system can be prolonged to last many hours by similar covalent modifications which are self-reinforcing (pathway 2), as in the case of autocatalytic phosphorylation of a protein kinase. Unlike these covalent modification mechanisms (pathways 1 and 2), the acquisition of long-term memory lasting more than 1 day (pathways 3 and 4) is dependent on the induction of new proteins (■, ▲). This induction is initiated by second messengers involved in short-term memory, which modify trans-acting regulators (open box linked to open circle) that activate both 'early effector' and 'early regulatory' genes. It is the induced synthesis of the proteins encoded by these genes, the early effector (11) and the early regulatory (A) proteins, that is blocked by the inhibition of protein synthesis during learning. Memory lasting for days is retained by the half-life of the effector proteins of early effector genes (pathway 3). Memory lasting weeks and months, longer than the half-life of effector proteins, is induced by the early regulatory genes whose protein products (which we call nuclear signals) trigger the maintained expression of late effector genes (pathway 4). Some of these additional acquisition steps (pathways 3 and 4) may require reinforcement by cytoplasmic signals to permit transition from shorter- to longer-term memory systems.

self-reinforcing mechanism to give a time course intermediate between short- and long-term memory (Fig. 1, pathway 2).

Induced proteins

We believe the sensitivity of long-term memory (lasting more than 1 day) to translational and transcriptional inhibitors during learning is best accounted for by inductive mechanisms, especially because the second messengers induced during learning (and responsible for the shorter forms of memory) are known to be potent gene activators in other systems^{25,26} (Fig. 1, pathways 3 and 4).

Particularly relevant for the discusson of learning are the peptide and biogenic amine hormones that activate receptors linked to enzymes involved in the synthesis of intracellular messengers. The detailed mechanisms by which these second messengers then regulate gene expression are unknown, but it is believed that they modify trans-acting regulators of transcription by either leading to their phosphorylation or binding to them directly, in a manner analogous to the binding of CAP protein by cyclic AMP in Escherichia coli^{27,28}. The modified transcription regulators could then act on enhancer DNA sequences of structural genes for long-term memory, much as do the DNA-binding proteins that mediate the transcriptional response to steroid hormones or heat shock^{29,30} (Fig. 1, pathway 3). With certain hormones, gene induction is relatively transient and parallels the period during which the hormone is present³¹. The duration of the physiological response is then carried by the stability of the mRNA and the half-life of the protein products. In the case of neurones, where the average half-life of protein is several days, the acquisition process for memory lasting days need, therefore, involve only transient activation of effector genes since the retention of memory could be accounted for by the turnover rate of the induced mRNA and protein products (Fig. 1, pathway 3). These considerations lead us to suggest that it will be important to look for alterations in gene expression, not only during the maintenance phase of memory but, more importantly, during the acquisition phase of memory, that is, during the learning process itself.

One objection to the possibility of genomic regulation of long-term memory that is sometimes raised relates to the question: how can a genomic change can lead to long-term alterations in some synapses of a neurone and not others? We suggest that synapse-specific alterations represent a special case of a larger issue frequently encountered in cell biology—the targeting of specific proteins to one rather than another site in the cell³²⁻³⁴. This problem is shared in many other contexts of cell biology. The transient modification at a given synapse produced by short-term memory could allow protein targeting to, recognition by, and stabilization at, that synapse.

Nuclear signals

Memories lasting many days to years clearly persist longer than the half-life of most proteins. In these cases, it is attractive to think of mechanisms for retention that are independent of protein and mRNA turnover, but which depend on persistent, rather transient changes in transcriptional state, changes that are maintained by cooperative or self-reinforcing mechanisms^{35,36} (Fig. 1, pathway 4). These mechanisms are used in cellular differentiation. Indeed, the often-drawn parallel between long-term memory and cellular differentiation³⁷⁻³⁹ has been strengthened recently by morphological studies of long-term sensitization of the gill-withdrawal reflex of *Aplysia*⁴⁰ and of long-term potentiation in the hippocampus⁴¹ which indicate that long-term memory is associated with growth of synaptic contacts.

Furthermore, the time window so characteristic of memory acquisition is also found in developmental processes in which 'early' genes act as regulators for the expression of 'late' effector genes. For example, the induction of growth and moulting in insects by ecdysone has been shown to alter the expression of

early genes whose induction regulates the expression of late genes. If ecdysone is given together with a protein synthesis inhibitor, the early genes are induced but the late ones are not; if the inhibitor is given several hours later, the late genes are induced normally⁴². A similar class of early genes has been studied more extensively in adenovirus where the nuclear oncogene E1A, an early gene, also regulates the expression of the late adenoviral genes⁴³. We suggest that protein synthesis inhibitors not only block the induction of effector proteins for memories lasting a few days, but also block the induction of nuclear signals used by early regulatory genes to activate long-lasting changes in the transcription or processing of the mRNA's of late effector genes. We believe, therefore, that much progress could be made by identifying possible nuclear signals used by early genes to communicate with late effector genes.

Particularly attractive candidates for nuclear signals in longterm memory acquisition are the products of 'competence' or 'immediate early genes' 44,45. These proteins are rapidly but transiently induced by hormones and growth factors whose prolonged presentation leads to cellular differentiation and growth. Although these early genes have yet to be shown to regulate the expression of specific effector genes in differentiation, the best-known members of this class, the proto-oncogenes c-fos and c-myc (which resemble the oncogene E1A), have several characteristics which may be relevant to nuclear signalling: (1), the genes respond to the specific cytoplasmic messengers shown to be involved in short-term memory, that is, cAMP, Ca²⁺ and diacyglycerol⁴⁶⁻⁴⁸. (2) The products of these genes are nuclear proteins⁴⁹ that are thought to affect transcription or mRNA processing⁵⁰. (3) The levels of the proteins and mRNA products, when induced, are only transiently increased because of their rapid turnover by degradative processes^{51,52}. (4) The oncogenic forms of these genes are capable of transforming cellular state⁴⁹.

We are not suggesting that c-fos and c-myc are the nuclear signals responsible for the establishment of memories lasting weeks; but we believe they represent prominent members of a large class of regulatory genes important for development (some of which may be induced during learning), whose protein products may have regulatory functions in the establishment of longer-lasting changes in cellular state. If induced nuclear regulatory proteins important for development prove also to be important for memory acquisition, it would have significance that would extend beyond the biology of learning. It would suggest the existence of common nuclear signalling systems, in the form of mRNA transcription and processing regulators, for long-lived cellular responses much as there are common cytoplasmic signalling systems for transient cellular responses.

Molecular reinforcement

We have proposed that the same extracellular signals that initiate short-term memory (Fig. 1, pathway 1) can initiate, through common intracellular messengers, additional acquisition steps for memory processes with more persistent retention mechanisms (Fig. 1, pathways 2-4). However, not every learning event gives rise to long-term memory. Often a single training trial produces only short-term memory. To produce long-term memory, repeated trials (repeated behavioural reinforcement) are required.

How is information for long-term memory distinguished from that for short-term memory? What are the molecular representations of the behavioural reinforcements necessary for initiating the various long-term memory processes (pathways 3 and 4 of Fig. 1)? To explain the specific activation of these additional acquisition steps, it will be necessary to determine whether the steps require quantitative changes in the levels or durations of the second messengers used in short-term memory, or whether qualitative changes are needed, such as the recruitment of other signalling systems, either cytoplasmic or nuclear. It will therefore be necessary not only to identify and characterize the effector

and regulatory genes whose transcription is activated during the acquisition of long-term memory, but also to delineate necessary molecular reinforcing events. However, the ability to pose some of the critical problems of long-term memory in molecular terms should allow an exploration of its various time courses in a variety of invertebrate and vertebrate learning systems, and thereby make it possible to explore long-term memory at its most fundamental level.

ARTICLES

Petrological and tectonic segmentation of the East Pacific Rise, 5°30′-14°30′ N

Charles H. Langmuir*, John F. Bender* & Rodey Batiza*

* Lamont-Doherty Geological Observatory, Palisades, New York 10964, USA † University of North Carolina at Charlotte, Charlotte, North Carolina 28223, USA * Washington University, St Louis, Missouri 63130, USA

Lavas from the fast-spreading East Pacific Rise are geochemically diverse even within a single tectonically defined spreading cell. Within such spreading cells, small offsets of the rise axis are often boundaries between petrologically distinct magmatic units which must be supplied independently from beneath the ocean crust. Volcanics erupted near the small offsets can have chemical characteristics similar to those previously found near transform faults.

IN April 1985, we carried out an extensive dredging program of the East Pacific Rise (EPR) between 5°30' N and 14°30' N. This region of the EPR is fast-spreading (9-11 cm yr⁻¹ full rate) and contains two major transform faults, the Siqueiros at 8°22' N and the Clipperton at 10°20' N (Fig. 1). There are several smaller offsets identified by Macdonald et al.1, which they named overlapping spreading centres (OSCs). Lonsdale^{2,3} identified similar features between 5°30' N and Siqueiros, which he called nontransform offsets. Our program was designed to examine the effects of transforms and smaller offsets on the chemistry of ocean ridge basalts, and through the chemistry to improve our understanding of magmatic processes along ocean ridges. Another aim of the study was to sample a substantial length of a fast-spreading ridge to test ideas about the relationship between spreading rate and the degree of observed mantle heterogeneity⁴⁻⁹.

Previous work on the chemistry of ocean ridge basalts erupted near transform faults suggested that proximity to transforms leads to several petrological effects, including cooler magmatic temperatures 10-12, eruption of a wider range of composition 12-15, higher-pressure fractionation 16,17 and slightly smaller extents of melting^{13,16}, which can lead to eruption of 'enriched' basalts when a veined mantle is present. These petrological effects, which collectively can be called a transform fault effect (TFE), make sense in terms of the cooling of lithosphere and asthenosphere that results from truncation of a spreading ridge by an offset 16,18. If these various effects are caused by lithospheric and asthenospheric cooling, the magnitude of the effect should correlate with the temperature (and hence, age) of the truncating lithosphere.

Earlier work also showed that there were abrupt changes in major and trace element chemistry across some transform faults

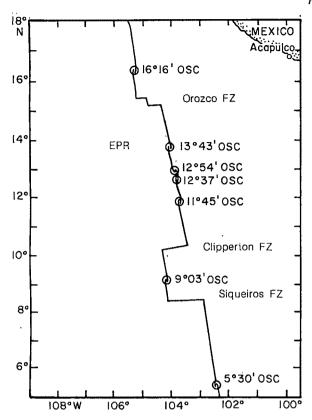

Fig. 1 Map showing general location of CHEPR expedition on the EPR, modified after ref. 1. The major transforms and overlapping spreading centres are indicated.

('transform discontinuities') at slow- and medium-spreading ridges 16,19,20. On this basis, it appeared that transforms might separate coherent geochemical units—lengths of ridge crest along which basalts are chemically related by crystal fractionation or different extents of melting 16. This idea, however, was based on sampling immediately adjacent to transforms, and needed to be tested by closely spaced sampling of a series of transform-bounded ridge segments.

The petrological variations associated with spreading centre offsets are just one aspect of a more general problem concerning the magmatic and tectonic segmentation of ocean ridges. Schouten and Klitgord²¹ introduced the useful concept of 'spreading cells' to describe transform-bounded ridge segments, and they showed that, in the Atlantic, spreading cells could be long-lived tectonic units. Francheteau and Ballard²² suggested that large portions of the EPR (~300 km) may be a single cell, although Ballard et al.²³ also noted the existence of secondary topographic highs separated by 'relay zones'. It has also been suggested 1.² that segmentation of the EPR needed to be considered in the context of both OSCs and transform faults, and thus could be <300 km.

The spreading cell idea has gradually evolved into a general magmatic model for ocean ridges. The centrepiece of this model is that there are magmatic injection centres regularly spaced along the ridge axis which correspond with long-wavelength bathymetric highs^{22,24,26}. Magma moves out from the central injection point along the ridge in a manner analogous to the observed rift eruptions on Iceland²⁵. Such an idea has received support from bathymetric studies²², from the location of hydrothermal fields^{22,26}, from interpretation of multi-channel seismic results²⁷, and from theoretical consideration of potential Rayleigh-Taylor instabilities during melt production beneath ocean ridges^{24,26,28}. In its simplest form, this central injection model predicts that the temperature of eruption of lavas should decrease regularly from a maximum at the bathymetric high at

the centre of a spreading cell to lower temperatures at the boundaries²⁹.

A contrasting, but not mutually exclusive idea, is that magma supply is not confined to the centres of long-wavelength cells, but that there are multiple injection centres distributed along the ridge, with edge effects at offsets which locally lead to cooler temperatures and possibly lower extents of melting (see refs 13-15; ref. 16, Fig. 12). The multiple injection model predicts less systematic long-wavelength variations in temperature and chemistry along axis except in the vicinity of large offsets, where the cold edge effect leads to lower-temperature lavas.

Thompson et al.29 recently presented preliminary petrological and photographic results from a short segment of the EPR between 10°20' and 11°45' N. They found at least five different basalt types, and suggested that they were separated into two discrete geographical units with edges at the Clipperton transform and the two OSCs identified by Macdonald et al.1. They also suggested that their data strongly supported the central injection model, and that each bathymetric high between OSCs or transforms was a single injection centre, away from which magmas became progressively more fractionated because of cooling during passage down axis. Inspection of their figures, however, reveals that the data show a narrow range in degree of fractionation $((Mg/Mg+Fe)=54\pm3(1\sigma))$ except for the dredge locations within 30 km of the Clipperton transform fault. In addition, there are at least two distinct magma types on each bathymetric high, which could be interpreted as evidence against the central injection model. Thus their data do not clearly discriminate between the central injection and multiple injection hypotheses.

Our dredging program was designed to recover samples on the appropriate scale to address the petrological significance of transform faults and smaller ridge offsets, and to discriminate between central injection and multiple injection models of ocean crust formation. The results and discussion which follow are the first-order results based on ~250 shipboard analyses of glass chips, supplemented by ~150 new major and trace element analyses on shore of hand-picked glass powders and 50 analyses of rare-earth elements (REE) by isotope dilution and neutron activation. A fuller evaluation based on data from chemical, mineralogical and isotopic studies will be given elsewhere.

Results

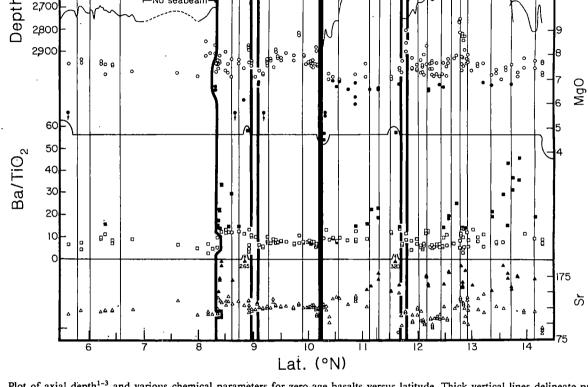

During the cruise, there were 122 successful dredges along 980 km of the EPR. Most of the dredge sites were located using a 12-kHz wide-beam echo sounder, conventional satellite navigation and large-scale versions of Sea Beam maps provided by Jeff Fox and Peter Lonsdale. All dredges were thoroughly described, and representative samples (~8 per dredge) were cut and had glass removed on board. Dredge tracks were usually made along axis and were usually kept to <1 km. One to four glasses per dredge were chemically analysed on board with a direct-current plasma emission spectrometer. The on-board analyses enabled us to determine where the significant changes in chemistry were occurring and to sample those areas more extensively.

Axial depth and linearity. A longitudinal profile of axial depth in our study area is shown in Fig. 2. The minimum depth was picked approximately every 2' of latitude from large-scale versions of the Sea Beam charts^{1,2}, and from our shipboard echo sounder data where there was no Sea Beam data between 7° N and the Siqueiros fracture zone. Macdonald et al.¹ pointed out many of the critical features of axial depth north of the Siqueiros transform. In particular, they noted the correspondence of OSCs with local maxima in axial depth. Although most of the depth profile in Fig. 2 is directly derived from the Macdonald et al.¹ maps, it differs from their profile in subtle but important ways. In particular, the Fig. 2 profile plots a single minimum depth except where two overlapping limbs of the EPR are completely unambiguous. The petrological data do not support the existence

Fig. 2 Plot of axial depth¹⁻³ and various chemical parameters for zero-age basalts versus latitude. Thick vertical lines delineate proposed spreading cell margins at the major OSCs and the two transform faults. Thinner vertical lines occur at small-offset OSCs and 'deviations from axial linearity' (devals) along the EPR, Filled symbols are for samples with MgO <7%, Ba/TiO₂ >14 and Sr >150 p.p.m., respectively. Ba/TiO₂ is a ratio similar to La/Sm. Normal, depleted ocean ridge basalts usually have Ba/TiO₂ ratios of 4-8. Enriched MORB with (La/Sm)_N>1 generally have Ba/TiO₂>23. Most chemical data were determined at sea by plasma emission spectrometry. Approximately 50 mg of glass chips were run for SiO₂, Al₂O₃, CaO, Na₂O, FeO, MgO, TiO₂, Sr and Ba. Because of approximate weights, sums were normalized to 99.5%. Precision based on 10 replicate analyses of a standard run on board as an unknown throughout the cruise was SiO₂, 0.5%; Al₂O₃, 2%; FeO, 1%; MgO, 1.5%; CaO, 2%; Na₂O, 1.5%; TiO₂, 2%; Sr, 2%; Ba, 10%. All data are 1σ in relative per cent (50.0±0.25 for SiO₂). Accuracy, based on samples rerun at Lamont, was worse than precision, and there were slight biases of as much as 3% relative for Na₂O and Sr. Some Ba values at sea were anomalously high, which we attribute to contamination with Mn-oxide rinds. Most high-Ba samples have been rerun at Lamont.

of an OSC at 11°15' N, and that OSC has been omitted.

The four large offsets in the region conveniently divide the EPR into five long-wavelength features, separated by the heavy vertical lines in Fig. 2. Across three of the four large offsets for which depths from both sides are shown there are distinct steps of >100 m in the axial depth. From Clipperton to the north end of the study area the axial depth increases substantially approaching the large offsets, giving a 'domed' shape to the long-wavelength features. South of Clipperton, 'domes' are not obvious, although depths do increase over short distances approaching the 9°03′ OSC and the northern side of the Siqueiros transform. Superimposed on all the long-wavelength features are shorter-wavelength (~25 km) undulations. Some of the deep points of these undulations correspond to the small-offset OSCs of Macdonald et al.1, but most do not. For example, just south of Clipperton there are several pronounced local depth anomalies even though there are no small-offset OSCs.

Another way of viewing the EPR is to note the changes in its strike. Lonsdale^{2,3}, for example, noted several kinks in the EPR between 4° and 6°S, Macdonald *et al.*¹ noted a 'regional sinuosity', and Ballard *et al.*²³ noted the existence of short

segments of slightly varying strike separated by what they called 'relay zones'. These changes in strike often occur where there are local depth maxima.

The petrological results presented below suggest that some of the short-wavelength variations in axial strike and depth are magmatically significant. Many of the short-wavelength undulations may be individual small volcanoes. Our initial inclination was to try and preserve a direct connection between the short-wavelength petrologic segmentation of the EPR and the 'spreading cell' concept. However, the short-wavelength structure of the EPR is likely to be temporally variable, and a fundamental feature of the 'spreading cell' idea21 is its connection with long-lived tectonic fabric of the ocean floor. Therefore, 'spreading cell' might be an appropriate term for each of the five long-wavelength bathymetric features in this area. Boundaries of spreading cells would be transforms or large-offset OSCs; these boundaries are relatively long-lived and usually have a significant change in axial depth across them. In addition, we suggest that the boundaries of the short-wavelength features within spreading cells be called 'devals' (or 'deviations from axial linearity'). The term 'deval' would include kinks, bends

(which are more gradual changes in strike than kinks) and small ridge offsets with or without overlap. (After the cruise, Batiza and Margolis³⁰ named one type of deval a 'SNOO', or small non-overlapping offset, and proposed a stochastic-spreading genetic model to account for such features.) We introduce the term 'deval' because the boundaries of the short-wavelength features can be petrologically important, yet their morphologic expression is diverse. There is not always an offset or overlap, hence terms which rely on these words are not general enough. Positions of some prominent devals are indicated in Fig. 2. Devals cannot always be identified with certainty on Sea Beam contour maps because of navigational inaccuracies, the nature of the contouring algorithm, and the subjective judgements involved in fitting separate Sea Beam swaths together by hand. Thus we give several examples of the importance of devals but do not present a comprehensive catalogue of their occurrence. Temperature, axial depth and width. One aim of the dredging program was to determine if there were systematic changes in the chemistry of basalts with changing depth of the EPR axis. Figure 2 shows the range of MgO contents of 200 glasses from our 100 zero-age dredge hauls. The magnesium content of glasses is directly proportional to liquidus temperature when olivine is close to the liquidus, hence the variations in MgO approximately reflect the relative variations in the quenching temperature of

Figure 2 shows that there is no overall correlation between the depth of the rise axis and the MgO content of the erupted lavas. The EPR between Clipperton and the 11°45′ OSC is, in general, a shallow segment, and yet it has the lowest mean MgO (that is, lowest temperature of erupted lava), while the adjacent ridge segment between the 9°03′ OSC and Clipperton, at approximately the same depth, has the highest mean MgO.

For each spreading cell defined by the major offsets, there is no overall correlation between MgO and distance from the centre of the segment. Some of the highest-MgO lavas occur near the centres of three of the five long-wavelength features, but so do lavas with average MgO contents. High-MgO lavas also occur at some of the margins of these features. Low-MgO, and even high-SiO₂ lavas occur immediately adjacent to the northern side of the Clipperton transform, the 9°03′ OSC and the 5°30′ OSC, but andesites also occur midway between Siqueiros and the 9°03′ OSC. Thus, in some cases, there may be a tendency for the centres of spreading cells to erupt hotter magmas, and the edges to erupt cooler magmas, but the data are noisy.

It is possible that on a shorter wavelength, samples from the centres of some of the secondary highs have higher MgO (for example, 9°50' N, 12°15' N and just south of Siqueiros). In most cases, however, our dredge spacing is not close enough to examine the detailed chemical variations for the secondary highs separated by devals.

In contrast to the complex and irregular relationship between MgO and depth, there may be a correlation between the mean regional MgO content and the mean regional width of the rise axis (Fig. 3). This correlation is not apparent over very short distances and for some unusual areas, such as just south of the 9°03′ OSC where the axis is exceptionally broad, but does apply when data are averaged over distances of ~50 km.

Macdonald et al. inferred from axial geomorphology that the cross-sectional shape of the rise axis reflected the robustness of the magmatic budget. The width in Fig. 3 is a crude measure of cross-sectional shape, and thus confirms much of Macdonald et al.'s discussion. In general, where the EPR is narrow and triangular, such as north of Clipperton, it reflects relative starvation of the magmatic budget. Erupted lavas tend to be cooler and to have low MgO, and show a pronounced edge effect. Where the EPR is broad, such as south of Clipperton, the magma supply is robust, the mean MgO content is higher and there is no perceptible edge effect either in terms of bathymetry or chemistry. The EPR also shows a substantial change in depth approaching Clipperton on the north, but is remarkably constant

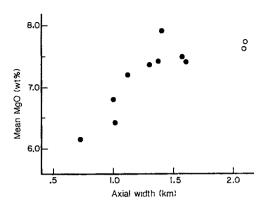

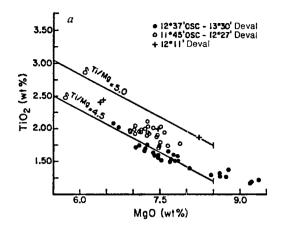

Fig. 3 Width of the EPR axis plotted against mean MgO content of the axis. Width was measured approximately every 2' of latitude as the distance between Sea Beam contours 40 m below the summit, using the maps from refs. 1-3. Standard deviations on the width estimated from this method are large, and the correlation should be regarded as qualitative.

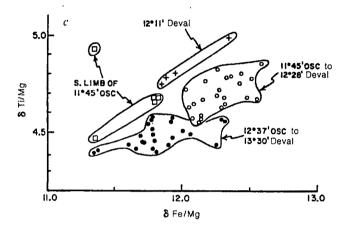

in depth on the south. Thus it may be the slope of the depth along axis rather than the absolute depth that correlates with magmatic temperatures. The bathymetry, shape of the rise axis and chemistry, therefore, do appear to be related, and reflect a balance between magma supply and edge effects. The balance can be highly variable even over short distances, such as across the Clipperton transform, and need not be related to position along a long-wavelength bathymetric feature.

As axial width seems to reflect the magmatic budget, one might expect a correlation between axial width and the presence of hydrothermal activity. It is also intriguing to speculate that the axial shape may reflect the width or depth of axial magma chambers.

Trace element geochemistry. Figure 2 also shows variations in Ba/TiO₂ ratios and Sr content of the basalt glasses. Both these parameters, but especially the Ba/TiO2 ratio, can be indices of enrichment of the mantle source. Ba/TiO2 is analogous to and correlates with the better known (La/Sm)_N ratio³¹. Normal ('N-type') MORB (mid-ocean-ridge basalt) glasses from both the Atlantic (~23 °N, 54 °N) and the Pacific (23° N and 44° N) have Ba/TiO₂ ratios between 2 and 12. Slightly more enriched, or transitional ('T-type') MORB, like those from the FAMOUS area along the Mid-Atlantic Ridge, have Ba/TiO2 ratios between 25 and 40. As Fig. 2 shows, several discrete lengths of ridge in our study area have Ba/TiO₂ ratios <12. Such N-type MORB occur from the 5°30' OSC to Siqueiros, from the 9°03' OSC north to Clipperton, and for the first 50 km north of Clipperton. From the 11°45' OSC to just south of the 12°37' OSC, 13 out of 15 dredges are N-type. Thus we recovered exclusively normal MORB from about two-thirds of the ridge length surveyed.

Surprisingly, one-third of the length of the EPR in this region contains at least some basalts more enriched than normal MORB. Such basalts occur from Sigueiros to the 9°03′ OSC, from a deval at 11°08' to the 11°45' OSC, around the 12°37' OSC, and around the 13°43′ OSC. In terms of regional distribution, the portions of the EPR which contain relatively enriched basalts are not systematically distributed with respect to the longwavelength bathymetric features discussed above. The most enriched basalts in the region occur just south of the large OSCs at 11°45' N and 9°03' N. Some basalts recovered near all of the OSCs in our study region (excluding 11°15') are more enriched than those recovered from the adjoining ridge segments. However, not every sample near OSCs is enriched. Devals also can be the location of relatively enriched basalts. In particular, basalts from the 8°37', 12°11' and 13°20' devals are more enriched than basalts from the axis immediately to the north and south (see Figs 2 and 5).

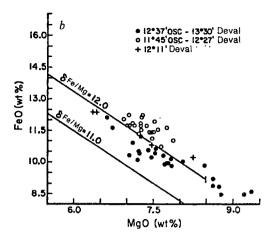

Fig. 4 Demonstration of major element variability along the EPR and the nature of the δ parameters. a, b, MgO/FeO and MgO/TiO₂ diagrams, all oxides in weight per cent. When the axes are rotated such that x' is parallel to the low-pressure fractionation path, then y', which is the δ value, reflects differences in the fractionation paths. Lines parallel to the x'-axis at different values of y' ($+\delta$) are shown for illustration. Samples with different δ values cannot be related to one another by low-pressure fractionation. c, Plot of δ Fe/Mg versus δ Ti/Mg showing distinct major element characteristics of different ridge segments. Samples from 12° to 12°28′ are completely distinct from those recovered between 12°37′ to 13°20′ N. Samples from near the deval at 12°11′ N plot separately, as do samples from south of the 11°45′ OSC.

The most notable feature of these data is the large number of occurrences of T-type MORB, and the significant number of dredges which recovered both T-type and N-type MORB. In the North Atlantic, T-type MORB are restricted to regions near hotspots, even where there are large offset transforms^{31,32}. Extensively sampled regions near the Kane fracture zone, for example, have yielded exclusively N-type MORB (ref. 32 and C.H.L. unpublished data). The fact that there are large regions with no enriched MORB, and discrete regions where enriched MORB are found, suggests that the mantle beneath this region of the EPR is not ubiquitously veined with enriched material.

Previously, it has been proposed that fast-spreading ridges are more homogeneous in their chemistry than slow-spreading ridges^{4,5,7}. The data in Fig. 2 demonstrate that basalt chemistry on a substantial portion of the EPR is not homogeneous, but instead is highly variable. Indeed, the mean Ba/TiO2 and the distribution of enriched material on the EPR between Siqueiros and 14° N is very similar to the ratio that can be inferred from rare-earth data from the South Atlantic, where there are multiple off-axis hotspots^{33,34}. These new data from the EPR are difficult to reconcile with correlations between spreading rate and the extent of geochemical variability which have been previously postulated. The data show that geochemical enrichment is not restricted to off-axis seamounts^{8,35}, but is quite common on axis as well. Thus, models which attempt to explain normal basalts on axis and both normal and enriched basalts off axis^{8,35,36} may need to be re-evaluated. Note, however, that the enriched basalts at zero age are preferentially located near offsets. Thus there may be lower extents of melting of a veined mantle beneath the offsets-suggesting that the offsets are at the margins of mantle melting anomalies. This explanation of the enrichment would be similar to that proposed for seamounts on older crust^{8,35}, but the spatial systematics leading to enriched basalts would occur

parallel rather than perpendicular to the rise axis. The remarkable consequence of this explanation is that even devals may be located at the margins of zones of mantle melting.

Chemical discontinuities across ridge offsets. The Sr and Ba/TiO₂ data in Fig. 2 show several abrupt, as well as some less abrupt, chemical changes across ridge offsets. There are prominent, abrupt chemical changes across the Siqueiros transform and the 11°45′ OSC. The 9°03′ OSC and 12°37′ OSC also bound distinct regions in Ba/TiO₂, but there is chemical 'noise' in the immediate vicinity of the boundary. A deval at 11°08′ divides discrete chemical regions as well. (Thompson et al.²⁹ suggested the 11°15′ OSC was a boundary, but we have two dredges, one at 11°10′ and the other at 11°20′, which have similar chemistry, suggesting that the actual boundary is south of 11°10′.)

The marked discontinuities in trace elements are also present in major elements-and the major elements reveal many more subtle discontinuities. Major elements are strongly affected by crystal fractionation, and usually suites of samples are required to define a regional trend, which can then be compared to another large region (see ref. 31). An example of such an approach is shown in Fig. 4a, b, where glasses from north of the 11°45' OSC to south of the 12°27' kink are compared with glasses from north of the 12°37' OSC to the 13°20' N bend. These illustrate a gross chemical distinction between these two regions, but it is useful to consider more detailed variations along axis which are not readily apparent from a presentation such as Fig. 4a, b. This can be done by rotating the axes so that the new reference frame has its x'-axis approximately parallel to the liquid line of descent after plagioclase has joined olivine on the liquidus, that is, for samples with ≤8.5% MgO. The values along the rotated y'-axis are given the δ notation because they reflect differences in the characteristic levels of Fe, Ti or Na of the various liquid lines of descent.

Figure 4c illustrates with major elements the discontinuities across the 11°45′ OSC and the 12°37′ OSC. The dredges from near the 12°11′ deval are distinct from the other data in the 11°45′ to 12°37′ ridge segment. Noting this distinction while at sea, we decided to halve our dredge spacing for this ridge segment to see if we could resolve smaller-scale segmentation. This segment was ideal for such a test, as there was an extended length of the EPR with no OSCs.

Figure 5 shows the results of this smaller-scale study. On the basis of the δ Ti/Mg parameter, this 50-km ridge segment appears to consist of three distinct chemical populations which are not related to one another by low-pressure fractionation processes. (One of the two sample groups from a single dredge appears to violate the regularity.) A small volcanic edifice with a relief of \sim 50 m and length of \sim 10 km (see Fig. 5) appears to consist of material with higher Ba/TiO₂ and δ Ti/Mg than the EPR immediately to the north and south. This small volcano is centred on the 12°11′ deval.

This small scale of petrological segmentation is not an isolated phenomenon. Figure 6 shows data for the ridge segment between Clipperton and the 9°17′ deval. This ridge segment is more homogenous in general than the segments which contain enriched basalts. There is a deval near 9°53′ N. Basalts from south of this feature are distinguishable from basalts north of it both in major and rare-earth elements. In both cases, each group is quite homogeneous, except right at the edges of the segments. Thus, in this region a deval separates two discrete petrological units.

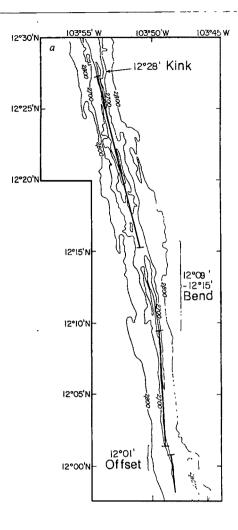

Occurrence of high-silica glasses. Glasses ranging in composition from basaltic andesite with 53% silica to dacite with almost 70% silica were recovered in three on-axis dredges and one off-axis dredge. Of these four dredges, three of them were near the major offsets—just north of the 9°03' OSC, just north of the 5°30' OSC and just north of Clipperton. Previously, high-SiO₂ glasses from the ocean flow have been recovered primarily from behind propagating rifts 14,37. Although other models which would lead to high-SiO₂ lavas are feasible, the occurrences on the northern limbs of these large-offset OSCs may imply that these limbs are propagating southwards. (On the basis of bottom photography, Thompson et al.29 also suggested that the east limb of the 11°45' OSC may also be propagating southward and Hekinian et al.40 suggested that the western limb of the 12°54' OSC may be propagating southward.) The fourth occurrence of high-SiO₂ glass is even more intriguing as it occurs 40 km north of the Siqueiros transform fault (Fig. 6d). It is not close to a major offset, but occurs just north of the deval at 8°37′ N (Fig. 6d). South of the deval are two dredges with normal basalts with no anomalous enrichment. At the deval there is slightly enriched basalt with higher light-rare-earth concentrations and Ba/TiO₂ ratio. The andesite occurrence is exactly analogous to the other occurrences of high-silica lavas (it is on the northern side of a right lateral offset), except that the offset is a deval rather than an OSC or transform.

Discussion

Recent studies have shown that there are several chemical effects which are often associated with transform faults; the results presented above suggest that chemical variations around some OSCs have many of these same characteristics. OSCs serve as the locus for the eruption of enriched basalts; more primitive, more differentiated and even silicic volcanics occur in their vicinity; and they serve as boundaries between chemically distinct ridge segments.

What is even more remarkable is that many of the chemical effects characteristic of transforms can also be present at very small bathymetric offsets (devals) which have only recently been able to be resolved as offsets with along-axis Sea Beam data^{1,2,23}.

The EPR thus seems to be magmatically segmented into petrological units which can have as boundaries, transforms, OSCs and devals. This segmentation is an order of magnitude

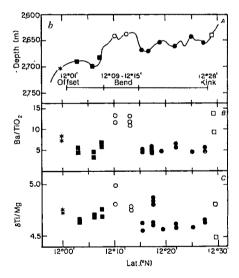

Fig. 5 Documentation of the fine scale of magmatic segmentation which can be present along the EPR. a, Sea Beam map¹ of the EPR from 12° to 12°30′ N. Locations of deviations from axial linearity (devals) are indicated. b, A, a depth profile of the axis and the dredge locations. B, Ba/TiO₂ ratios for basalt glasses from the dredges. C, δ Ti/Mg for the same glasses (see Fig. 4 for explanation of δ Ti/Mg). Note that with the exception of one sample group from the dredge at ~12°17′ N, the data separate into distinct, regionally coherent groups.

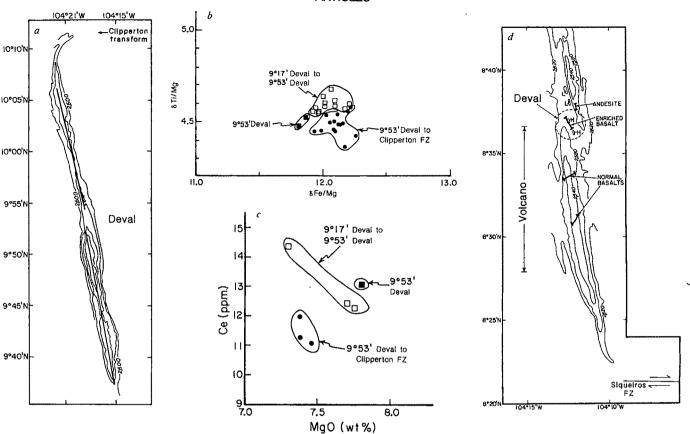

Fig. 6 a, Sea Beam map¹ of the EPR just south of the Clipperton transform fault. Note that the EPR seems to consist of a series of sausage-shaped volcanoes. b, Plot of δTi/Mg versus δFe/Mg, showing the distinct major element chemistry across the 9°53′ deval. c, Ce versus MgO, showing the distinction in rare-earth elements across the 9°53′ Deval. Ce was determined by isotope dilution. d, Sausage-shaped volcano north of the Siqueiros transform showing the systematic locations of andesite, normal basalt and enriched basalt.

smaller than long-lived spreading cells. For example, we find that the spreading cell of Francheteau and Ballard²², which includes the whole dome between 11°45′ N and the Orozco fracture zone, is made up of as many as 10 much smaller discrete magmatic segments. The two axial volcanoes of Lonsdale³ between the Gofar and Yaquina transforms may actually be 10 smaller-scale volcanic edifices. Each small segment of rise crest has its own bathymetric expression, and may have its own distinctive chemical signature.

Posible origins of devals. The origin of these features poses an interesting problem which is dependent on the interaction of magma supply with the stress regime at the rise axis, and which must relate in some way to OSCs. There is conceptual continuity across the range from large OSCs with substantial overlap and a deep overlap basin, to small OSCs with almost no decipherable basin, to devals with or without overlaps, and with no basin. This progression naturally suggests a familial relationship among these features and that a general concept may apply to all of them. The petrological data suggest that a starting point for such concepts should be that all the features are boundaries between regions with separate magma supply.

One possibility would be that the size and importance of the various offsets relates to the depth and scale of mantle upwelling. Transforms separate deep upwelling regions, and can remain distinct for up to 10^8 yr (ref. 21). At the other extreme, devals may reflect the last stage of melt segregation, at which small batches of magma ascend from beneath the crust to form axial magma chambers and associated volcanic cones. Individual devals may have a lifetime of $\leq 10^4$ - 10^5 yr. Large-offset OSCs would be intermediate features with intermediate lifetimes.

An important question is whether offsets propagate. Transforms in this region are quite stable and long-lived. The existence

of a volcanic edifice centred on a deval at 12°11' N leads us to speculate that new magmatic pulses may sometimes nucleate at a deval, and that (at least some) devals may not propagate but may be simply covered up by new volcanic construction. Thus, a deval may mark the edge of a constructional volcanic event, and may provide a nucleation site for the next volcanic pulse. Implications for OSCs. The discontinuities in chemistry documented above place constraints on models for the origin of OSCs. Both models^{1,2} suggest that OSCs separate regions of independent magma supply, and in this respect our data agree. Lonsdale's model², however, relies on the presence of a large magma chamber beneath OSCs, and in this respect is difficult to reconcile with the petrological data. Macdonald et al. suggested magma chambers were continuous beneath small-offset OSCs and that even for large-offset OSCs the magma chamber would become continuous once one OSC linked with another. They suggested that OSCs develop when a magma pulse interacts with this sinuosity of the ridge axis, and that the sinuosity results from previous OSCs. Thus, in their model OSCs are intimately connected with axial magma chambers. Our data suggest that OSCs, particularly those of large offset, may result from being at the margins of deep upwelling zones with fairly long wavelengths-the relationship with magma chambers is not at all clear. Between such large-offset OSCs there may be multiple devals which never were and never will become OSCs. Thus, large-offset OSCs and devals may reflect different stages, scales and depths of magma supply.

Note that there may be an asymmetry to the types of rocks recovered around the large-offset OSCs. All silicic rocks are on northern limbs. The most enriched rocks are on southern limbs, approximately on strike with the northern limbs. To the extent that silicic rocks reflect rift propagation, this suggests that the

northern limbs are propagating southwards. The southern limbs may be stagnating^{2,3}. The stagnating rift may be the locus of seamount formation because it is no longer an active spreading centre and hence eruptions pile up on the crust and form seamounts. Enriched basalt occasionally may occur because the OSCs are at the margins of the melting anomaly in the mantle where the extent of melting is less, and hence small-scale heterogeneities may be sampled. Sinton et al.37 have pointed out that absolute plate motions may be important for understanding some aspects of propagating rifts and Schouten et al.38 have attempted to relate off-axis seamount trends to absolute plate motions. Intriguingly, if all the northern limbs on this portion of the EPR are propagating southwards, then there may be a relationship with absolute plate motions, which have a northward component in this region.

Axial magma chambers. These petrological data seem to provide tight constants on the scale of mixing and homogenization of EPR lavas. The small, discrete chemical units along axis, some of which appear to require tapping of heterogeneous mantle, show that the processes of basalt genesis, including magma formation, segregation from the mantle, injection into the crust and eruption onto the ocean floor, do not homogenize EPR lavas. The only way that there could be a continuous axial magma chamber is if it has many separate regions of supply from below the crust and is not well mixed. Basaltic magma chambers in many geochemical models are envisaged as efficient mixing machines which buffer and homogenize magmas³⁹. This geochemical concept of a magma chamber is difficult to reconcile with our data. If, on the other hand, a physical magma chamber does exist, then the magma chamber must be variously fed. incompletely mixed, and hence substantially zoned and laterally heterogenous in its composition. However, if this were the case, why are most of the petrological data systematically distributed with respect to devals and OSCs? Therefore, while the data do not strictly require the physical absence of a magma chamber, they would be most consistent with magma chambers that are discontinuous, even with single spreading cells.

Conclusions

Systematic dredging of the EPR with an average spacing of 8 km has allowed a definition of the scale of magmatic diversity and segmentation along 700 km of a fast-spreading ridge. The data have definite implications for the two models of ocean crust formation discussed. Central supply of magma to the crust on the scale of spreading cells, even when such cells are defined by OSCs with finite offset, is difficult to reconcile with the data. Instead there seem to be multiple injection zones from the mantle into the crust. This does not mean that there are no petrological regularities with respect to spreading cells. Note that the most pronounced chemical offsets and most pronounced edge effects occur at the spreading cell boundaries, where there are also

discontinuities in axial depth. The long-wavelength anomalies must relate to the temperature structure and mass transfer processes within the underlying mantle. Apparently the mantle is variable on a much smaller scale than the long-wavelength anomalies, and this variability can be preserved through the crust formation process.

The data also have important implications for the effects of transform faults on the petrological evolution of the ocean crust. The south side of the Clipperton transform, where there is a cold edge, apparently has no petrological edge effect, unless it is on the adjoining, older plate. In contrast, there can be pronounced edge effects at devals, where there is no cold edge. Thus, in many cases there are edge effects, but not cold edge effects. This means that the previous emphasis on the cold edge as an explanation of the petrological manifestations associated with transform faults (and possibly propagating rifts) needs to be re-evaluated. Some aspects of the edge effects may be concerned with along-axis systematics of upwelling, melt segregation and distribution in the crust, and magmatic edges may exist even when there are not tectonic cold edges 13,16 (hence the occurrence of edge effects at devals). The cycle of magma supply to the ocean crust also seems to be able to overwhelm the tectonic cold edge, such as is occurring south of Clipperton. It is not clear from our zero-age data whether the cold edge has a time-averaged effect which only over the short term can be dominated by the magmatic budget.

Finally, the data show that enriched basalts are common at zero age on this portion of the EPR, although they do seem to occur preferentially at offsets. The general concept of fastspreading ridges being more homogeneous than slow-spreading ridges such as the Mid-Atlantic Ridge is no longer valid.

We thank the other members of the CHEPR team: Emily Klein, Pat Castillo, Jerry Ross, Terri Smith, Dan Miller, Tim O'Hearn, Mike Thatcher, Alex Biesada, Eliesir Duarte and Ron Comer for hard work and dedication. Captain Tom Desjardins and the crew of R/V New Horizon were also very helpful. Collaboration with Emily Klein has contributed substantially to this work. Jeff Fox and Peter Lonsdale gave us large-scale versions of Sea Beam maps which were essential for precision dredging. Geoff Thompson, Bill Bryan and Jim Natland provided preliminary data from cruises to the EPR. Conversations with or reviews by Bill Bryan, Dave Christie, Bob Detrick, Dan Fornari, Jeff Fox, Fred Frey, Dick Hey, Ellen Kappel, Jill Karsten, Kim Kastens, Peter Lonsdale, Ken Macdonald, John Mutter, Jim Natland, Mike Perfit, Paul Robinson, Jean-Guy Schilling, Hans Schouten, John Sinton, Geoff Thompson, and Dave Walker were very useful. This work was supported by NSF grant OCE84-11448 to C.H.L. at Lamont-Doherty Geological Observatory and OCE84-09660 to J.F.B. at the University of North Carolina at Charlotte. The Seed Money program at Lamont-Doherty provided part of the funds necessary to carry out the shipboard analyses.

Global temperature variations between 1861 and 1984

P. D. Jones, T. M. L. Wigley & P. B. Wright*

Climatic Research Unit, School of Environmental Sciences, University of East Anglia, Norwich NR47TJ, UK

Recent homogenized near-surface temperature data over the land and oceans of both hemispheres during the past 130 years are combined to produce the first comprehensive estimates of global mean temperature. The results show little trend in the nineteenth century, marked warming to 1940, relatively steady conditions to the mid-1970s and a subsequent rapid warming. The warmest 3 years have all occurred in the 1980s.

GLOBAL mean surface air temperature is the most commonly used measure of the state of the climate system. When general issues of climatic change are addressed, global mean temperature change is often used as a yardstick; the age of the dinosaurs was warmer than today, the ice ages were colder, and so on. Paradoxically, in the present era of instrumental meteorology, with data coverage far better than at any earlier time, our knowledge of global mean temperature changes is still uncertain. Variations in global mean air temperature are of considerable importance, as they are a measure of the sensitivity of the climate system to external forcing factors such as changes in carbon dioxide concentration, solar output and the frequency of explosive volcanic eruptions. Quantifying the response of the climate to external forcing changes is a major goal of climatology and a prerequisite for predicting future climatic change. As a step towards this goal, we present here the first global synthesis of near-surface temperature measurements over the land and

Most earlier estimates of global and hemispheric mean temperature (see refs 1, 2) were based solely on data from land-based meteorological stations. Since >70% of the globe is ocean, one might suspect the global representativeness of such estimates, although on long timescales (≥decades) the thermal coupling between land and ocean should ensure that the land data largely mirror changes occurring over the oceans1. Recently, data from ships at sea collected for routine weather forecasting purposes, have been compiled by groups in the United Kingdom^{3,4} and the United States^{5,6}, and these data give us the potential to calculate improved estimates of global mean temperature. Apart from our own work⁷, the only previous attempt to analyse both land and marine data is that of Paltridge and Woodruff^{8,9}. These authors, however, failed to account for inhomogeneities in the marine data, which are substantial (see below and also refs 4 and 10). The quality and coverage of the land data they used was also less than adequate, but this is understandable because they were primarily interested in sea-surface temperature variations.

The land data we use are those from refs 11, 12. These have been carefully examined to detect and correct for non-climatic errors that may result from station shifts or instrument changes, changes in the methods used for calculating means, urban warming, and so on. Although problems still exist^{13,14}, the quality of these data is much better than that of material used in earlier studies. Area averages based on these data show medium to long timescale trends (≥10 yr) whose spatial consistency provides a strong pointer to the data's overall reliability^{1,11,12}. The marine data we employ are those in the COADS (Comprehensive Ocean Atmosphere Data Set) compilation⁶ which extends to 1979, and data from the Climate Analysis Center, NOAA,

for 1980-84. We use both sea surface temperatures (SST) and marine air temperatures (MAT).

Marine data problems

Both SST and MAT data contain 'inhomogeneities', variations resulting from non-climatic factors^{4.10,15}. For example, early SSTs were measured using water collected in uninsulated, canvas buckets, while more recent data come either from insulated bucket or cooling water intake measurements, with the latter considered to be 0.3-0.7 °C warmer than uninsulated bucket measurements¹⁰. For marine air temperatures, changes in the size and speed of ships, especially those increases associated with the sail to steam transition, are both thought to have influenced data homogeneity. In addition, many early air temperature observations were not taken in screened locations. Because of these non-climatic factors, both SST and MAT data must be corrected (or 'homogenized') to remove their effects.

Folland et al.4,16 and Folland and Kates17, using the UK Meteorological Office (UKMO) data bank3, attempted to overcome these problems by identifying specific sources of error, attempting to quantify these and using this information to make corrections to the raw gridded data. Such corrections have inherent uncertainties because of difficulties in their a priori quantification and a lack of knowledge of how most measurements were taken. Information on whether bucket or intake measurements were made has, in most cases, apparently been lost or never recorded. It has also been shown¹⁸ that supposedly homogeneous (that is bucket-only or intake-only) SST data series appear to have non-climatic changes that are similar to those found in mixed data series, suggesting that all historical data sets contain a mix of measurement types. Since 1945, however, it is generally assumed that available SST data contain a reasonably consistent mix of intake and bucket measurements18.

The Folland et al.⁴ corrected MAT and SST series have been compared with averages of land-based data by Jones et al.^{11,12}. Agreement is reasonable since the start of the twentieth century, although MAT values for the years 1942-45 appear to be too warm in both hemispheres. Before 1900, the marine and land series diverge markedly, with both marine series being about 0.3 °C warmer than the land data.

Correcting the COADS data

The COADS compilation contains some 63.25 million non-duplicated SST observations, of which 0.96 million have been 'trimmed' to remove extreme outliers⁵. While these are more data than in the UKMO SST set (which has about 46 million non-duplicated observations⁴), the effective area and density of coverage is very similar in both data sets. However, unlike the UKMO data set used by Folland *et al.*⁴, none of the data in COADS have been corrected for non-climatic effects. Our first task, therefore, was to homogenize the COADS data. We did

^{*} Present address: Max-Planck-Institut für Meteorologie, Bundesstrasse 55, 2000 Hamburg 13, FRG.

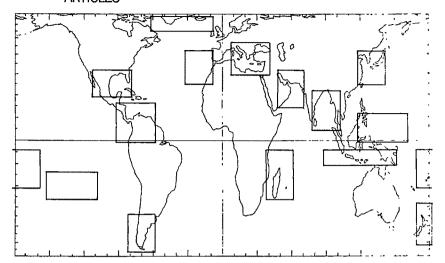

Fig. 1 Map showing the 15 regions where marine air temperatures and land-based temperatures were compared (Peters equal-area rectangular projection).

this by comparing marine and land data in areas where the two abut or overlap (coastal areas and around ocean islands).

The trimmed COADS data include monthly means and medians on a 2°×2° grid, together with the number of observations in a month and the mean observation date. We compressed the data onto a more manageable grid (5°×5° for MAT, 4°×10° for SST) after first eliminating values where the number and distribution of observations was likely to have produced unrepresentative monthly means, and expressed the values as anomalies from a 1950-79 reference period. As a test of data quality at this stage we calculated hemispheric mean values by appropriately weighting the gridded MAT and SST data (NH, Northern Hemisphere; SH, Southern Hemisphere). Year-to-year variations for these uncorrected data were found to be in excellent agreement with the UKMO corrected data (NHSST, r=0.86; NHMAT, r = 0.87; SHSST, r = 0.88; SHMAT, r = 0.75 over 1856-1979: correlation coefficients calculated using residuals from a 10-yr gaussian filter), but, as expected, the long-term (≥10 yr) fluctuations showed marked differences. Similar high frequency correlations between SST and MAT for the uncorrected COADS data (NH, r = 0.91; SH, r = 0.89) were higher than in the corrected UKMO data (NH, r = 0.81; SH, r = 0.80).

Because of the high SST-MAT correlation (see also ref. 19). SST data can be corrected by comparison with MAT data, once the latter have been corrected. For the MAT data, any attempt to assess, a priori, the magnitudes of errors arising from instrumental changes, changes in observation methods, and the effects of changes in ships' thermal inertia, speed and size (the latter determines the height at which observations were taken), must be fraught with uncertainty. Data reliability and long-term homogeneity can be far more convincingly demonstrated for the gridded land data than for the marine data because land station data homogeneities can be more easily identified, explained and corrected 11,12. We therefore use these data directly to correct the marine data. Fifteen regions (see Fig. 1) were chosen in which land and marine data are in close proximity. Area averages of annual mean MAT and land air temperature were calculated for each region using the uncorrected COADS data and the homogenized land data produced by Jones et $al.^{11,12}$. No attempt was made to consider night-time observations only, as used by Folland et al.4. In addition to the 15 pairs of area averages, annual mean coastal land time series were produced for both hemispheres and compared with the uncorrected hemispheric-mean MAT series.

The 17 land minus MAT time series were then examined for systematic differences between the land and marine data. For the period 1861-1979 (both marine and Southern Hemisphere land data are unrepresentative before 1861 because of poor data

coverage), five distinct periods could be discerned in all 15 regional land minus MAT time series and in the two hemispheric land minus MAT time series. The latter are shown in Fig. 2. The three main periods are: the period up to the 1880s when the MAT data appear to be too warm by 0.4-0.5 °C; the period from the 1900s to 1941 when the MAT data are too cold by 0.1-0.2 °C; and 1946-79 when there is no obvious bias. There is a strong upward trend in the land-minus-MAT difference between the mid 1880s and the late 1900s, and the war years, 1942-45, are marked by anomalously warm MAT values. The consistency between the hemispheres is clear from Fig. 2, and the land minus MAT data for the individual smaller regions, although showing greater inter-annual variability, all show the same features.

The nineteenth century land minus MAT data also show differences between the values before and after about 1873 (see Fig. 2). By examining land, MAT and SST data it can be shown that this difference is also likely to reflect a non-climatic

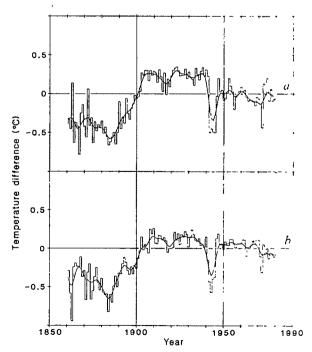

Fig. 2 Temperature differences: coastal land values minus uncorrected COADS marine air temperature values for the Northern (a) and Southern (b) Hemispheres. Smooth curves show 10-yr gaussian filtered values, padded at each end as described in ref. 11.

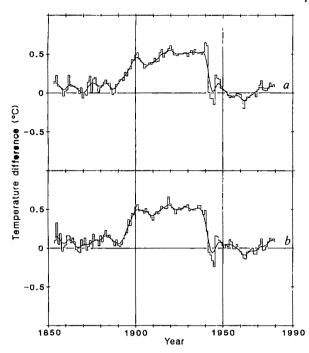

Fig. 3 Temperature differences: corrected marine air temperatures minus uncorrected sea surface temperatures for the Northern (a) and Southern (b) Hemispheres. Smooth curves show 10-yr gaussian filtered values.

inhomogeneity in either the MAT data or the land data, probably the former.

The means and standard deviations of the land minus MAT values are shown in Table 1. The consistency of these values strongly suggests that these land/MAT discrepancies are not climatic in origin. They may, therefore, be used to estimate annual correction factors for the MAT data in order to make these data compatible with the existing homogenized land data. Except for the 1942-45 period, when war conditions apparently prompted observers to measure temperature in unconventional locations⁴, the specific reasons for these non-climatic MAT fluctuations are not known. Although their reality cannot be questioned, there is clearly some uncertainty in the magnitude of the implied corrections.

The correction values we have used (added to the raw MAT data) are (°C): 1861-73, -0.40; 1874-89, -0.48; 1903-41, 0.17; 1942-45, -0.54; 1946-79, 0.0; with linear interpolation between

 \bar{X} = mean land minus MAT value; s = corresponding standard deviation defined by $s^2 = (Y-1)^{-1}\Sigma(X_i = \bar{X})^2$ where X_j is the value in year j, and Y is the number of years; $s(\bar{X})$ = standard deviation of the means defined by $(s(\bar{X}))^2 = (n-1)^{-1}\Sigma(\bar{X}_i - \bar{X})^2$ where n is the number of regions (6 or 9), \bar{X}_i is the mean for region i and \bar{X} is the average value of \bar{X}_i . The last line shows the inferred correction which was added to the uncorrected annual MAT data.

1889 and 1903. Slightly different corrections were judged necessary for Southern Hemisphere data between 1941 and 1945: 1941, -0.14; 1942-45, -0.44. Most of the transition dates for these correction factors, which are based on a number of considerations, could be altered slightly with no appreciable effect on the resulting corrected MAT values. Although the 0.08 °C difference in the MAT corrections before and after 1873 may be inappropriate if it arises from a land data inhomogeneity, we judge this to be unlikely. It has the effect of slightly reducing the magnitude of the long-term MAT warming between the period before 1873 and today. The corrections generally reflect the mean land minus MAT values shown in Table 1, but the precise values used and the transition dates also take MAT-SST comparisons into account. Our corrections differ markedly from those applied by Folland et al.4 to their night-time MAT data. This is a clear indication of incompatibilities between the corrected UKMO MAT data and the homogenized land data (see also refs 11 and 12).

Having corrected the MAT data, we can now estimate the SST corrections required to ensure overall compatibility between the land, MAT and SST data by comparing the corrected MAT and raw SST values. Table 2 and Fig. 3 show the hemispheric mean differences between the corrected MAT data and the raw SST data. As with the MAT analysis, three distinct periods can

Table 2. Comparison between corrected MAT data and uncorrected SST data

		1861-89	1903-41	1942-45	1946-79
NH	$ar{X}$	0.08	0.49	-0.07	0.02
	·s	0.08	0.08	0.07	0.09
SH	$ar{X}$	0.07	0.50	-0.14	0.02

 \bar{X} = mean MAT minus SST value; s = corresponding standard deviation. The correction is the number added to the uncorrected annual SST data.

be discerned: pre-1890 when the SST data are slightly but consistently cooler than the MAT data; 1903-41 when SSTs are markedly cooler than MATs; and post-1945 when there is no consistent difference. Rather complex transitions exist between these three phases. The MAT-SST difference curves are essentially the same in both hemispheres. This is a strong indication that the differences reflect non-climatic effects, and it provides a valuable consistency check on the MAT corrections.

The implied SST corrections, are (°C): 1861-89, 0.08; 1903-41, 0.49; 1942-45, -0.10; 1946-79, 0.0; with linear interpolation between 1889 and 1903. For 1941 we applied a slightly different correction in the Southern Hemisphere, 0.19 °C. As for MAT, these corrections also differ somewhat from those used by Folland et al.⁴. In their analysis, SST values were adjusted to ensure compatibility with corrected MAT values, just as we have done. However, since their corrected MAT values must differ noticeably from those produced here, differences in the SST corrections will, in part, reflect these MAT differences.

In our analysis, the difference between the twentieth century SST correction factor before 1941 and after 1946 is 0.49 °C. This difference is in the range (0.3-0.7 °C) generally accepted for the difference between uninsulated bucket and intake SST measurements ^{18,20,21}. The precise reasons for the differences that we obtain between the nineteenth century and early twentieth century MAT and SST corrections are uncertain. For MAT, the change is likely to be related to the transition from sail to steam. Between 1880 and 1910, the percentage of steamship tonnage as a fraction of total shipping tonnage rose from ~25 to 75% (ref. 22). Noticeable increases in ship speed occurred over the period 1880-1900, and in ship size over the period 1890-1910

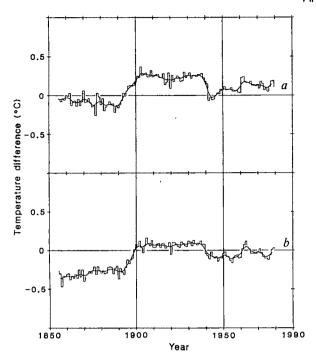

Fig. 4 Differences between the hemispheric-mean sea surface temperature values produced in the present work and those of Folland et al.⁴; Northern Hemisphere (a), Southern Hemisphere (b). Smooth curves show 10-yr gaussian filtered values. The implied warmth of the Folland et al. SH data relative to the NH (by ~ 0.2 °C), is due to their use of 1951-60 as a reference period. Conditions during this decade differed noticeably from the mean conditions during the reference period, 1950-79, used here (see

(ref. 22). These dates should be compared with the duration of the rising trends in land minus uncorrected-MAT data in both hemispheres shown in Fig. 2. Changes in MAT may be related to exposure changes attendant on the above, and to other changes in instrument exposure procedure which occurred over the same period. For SST, the main reasons for the change may be the standardization of the measuring technique and the introduction of more reliable instruments²³. It is also possible that, in the mid to late nineteenth century, many bucket temperatures were not taken in the shade²⁴. In addition, some of the earlier measurements may have been made with wooden rather than canvas buckets. The latter, being uninsulated and subject to evaporative cooling, produce lower temperature readings.

The overall differences between the hemispheric mean SST values produced here and those of Folland et al.4 are shown in Fig. 4. The results for an MAT comparison are similar. The discrepancies are large and comparable in magnitude to either set of corrections. The reasons for these differences stem mainly from the different correction factors applied to what are essentially similar raw data. Because there are several sources of data inhomogeneity, we have not attempted to correct for these individually. The result should be more complete than Folland et al.4 who attempted to make specific corrections for identified sources of inhomogeneity based on physical arguments. Our corrections synthesize the effects of several different factors. However, while they ensure compatibility between the marine and land data, the fact that the reasons for these corrections are uncertain must point towards some remaining uncertainty in our corrected marine data, especially in the nineteenth century.

Global mean temperatures ...

It is a relatively simple matter to produce estimates of annual global mean surface air temperature using the available (correc-

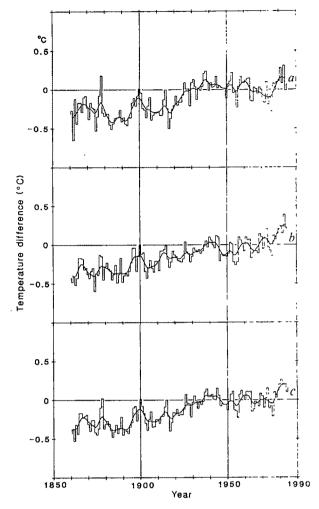

Fig. 5 Global (c) and hemispheric (Northern, a; Southern, b) annual mean temperature variations since 1861, based on seasurface temperature data to represent the marine domain and using weights corresponding approximately to the maximum coverage for the four domains (method two in the text). Smooth curves show 10-yr gaussian filtered values. 1980-84 values are based on SST data obtained from the Climate Analysis Center, U.S. National Oceanic and Atmospheric Administration (see ref. 29 for information about this data source). These data were adjusted to be compatible with the values in earlier years by comparing values in both hemispheres over the overlap period, 1970-79. The CAC data correlate highly with the COADS data (r=0.984 for the Northern Hemisphere mean and r=0.991 for the Southern Hemisphere mean).

ted) marine data and the most recent compilations of land data^{11,12}. There are three different ways in which global or hemispheric (land plus marine) averages can be calculated. The first method is to average only those grid point values (with appropriate cosine weighting) for which data exist. This is the way hemispheric means have been produced for the land data^{11,12}. The second and third methods assume that each of the four independent time series (NH and SH land and NH and SH marine, either SST or MAT) are, at all times, representative either of their maximum coverage or of the total areas of the four domains. The results obtained differ but little, and the use of either SST or MAT to represent the marine domains produces only minor differences. We therefore show only results using the second method based on SST data, obtained using

T global = 0.25NH land + 0.25NH SST + 0.2SH land + 0.3SH SST

(Fig. 5) where, after 1957, SH land includes Antarctic data from

Raper et al.25, updated. The insensitivity to the precise method of weighting arises because all time series are quite strongly

The reliability of the time series given in Fig. 5 as true hemispheric and global averages can be questioned because the spatial coverage, even at best, is less than 75% and because the coverage changes with time. Coverage is always much better in the Northern Hemisphere. Coverage before 1900 is generally less than one third of the globe, down to <20% in the 1860s. The question of representativeness of the land data has been considered in detail in refs 1, 11 and 12. Although marine coverage before 1900 is sparse, the spatial correlation length over the oceans is large and limited coverage should still give results representative of a much larger area. Nevertheless, there are large parts of the Southern Hemisphere that nearly always lack data, especially the southern oceans south of 45 °S and the whole of the southeastern Pacific (except near the South American coast). Before 1957, when most Antarctic data first became available, there are essentially no data at all for the globe south of 45 °S (refs 25, 26). Although this represents only ~15% of the area of the globe, temperature fluctuations at high latitudes are known to be larger than at lower latitudes and so can have a disproportionate effect on the global average^{12,27}. Any interpretation of Fig. 5 must bear in mind both these basic data deficiencies and the marine data uncertainties implied by

Fig. 4. We note, however, that the latter do not affect the gross features of the global mean changes observed this century.

The global curve is extremely interesting when viewed in the light of recent ideas of the causes of climatic change^{1,2}. The data show a long timescale warming trend, with the three warmest years being 1980, 1981 and 1983, and five of nine warmest years in the entire 134-yr record occurring after 1978. With regard to the hypothesized warming due to increasing concentrations of carbon dioxide and other greenhouse gases, the overall change is in the right direction and of the correct magnitude 1,7,28. However, the relatively steady conditions maintained between the late 1930s and mid 1970s requires either the existence of some compensating forcing factor or, possibly, a lower sensitivity to greenhouse gas changes than is generally accepted.

We thank particularly C. K. Folland, D. E. Parker, P. M. Kelly, T. P. Barnett and D. J. Shea for useful comments. We thank D. E. Parker and C. K. Folland (UK Meteorological Office) for access to unpublished data used in Fig. 4 Scott Woodruff (Environmental Research Laboratories, US National Oceanic and Atmospheric Administration) for an early copy of the trimmed COADS data set, and the Climate Analysis Center, US National Oceanic and Atmospheric Administration, for the recent marine data used in Fig. 5. This work was funded by the Carbon Dioxide Research Division, US Department of Energy, grant no. DE-FGO2-86-ER60397.

FTTERS TO NATURE

Observation of terrestrial orbital motion using the cosmic-ray Compton—Getting effect

D. J. Cutler* & D. E. Groom*

Department of Physics, University of Utah, Salt Lake City, Utah 84112, USA

* Present addresses: Instrumentation Laboratory, North 3939 Freya, Spokane Washington 99207, USA (D.J.C.); Supercollider Central Design Group, LBL 90-4040, Berkeley, California 94720, USA (D.E.G.)

Using underground observations, we have found a small diurnal amplitude modulation of the cosmic-ray muon intensity which agrees in amplitude and phase with a first-order relativistic effect due to the Earth's motion, as discussed by Compton and Getting more than fifty years ago. The parent particles are sufficiently rigid ($\sim 1.5 \, \mathrm{TeV}/c$) that solar and geomagnetic effects should be minor. The muon flux deep underground is relatively insensitive to near-surface meteorological effects, and temperature effects at production height would produce intensity variations nearly out of phase with the observed effect. Analysis of the arrival times of 5×10^8 muons during a period of 5.4 yr yields a fractional amplitude variation of $2.5^{+0.7}_{-0.6} \times 10^{-4}$, with a maximum near dawn, at $08:18\pm1.0$ h local mean solar time (LT). The expected amplitude is 3.40×10^{-4} , with the maximum at 06:00 LT.

Compton and Getting1 showed that a cosmic-ray detector with an energy threshold would observe an enhanced intensity when it moved along its direction of maximum sensitivity with respect to the rest frame of the cosmic-ray plasma. If the cosmicray energy distribution were a power law of the form $E^{-\gamma}$, then the fractional intensity enhancement above a fixed energy threshold should be

$$\frac{\Delta I(\theta)}{\langle I \rangle} = (2 + \gamma) \frac{v}{c} \cos \theta$$

where θ is the angle between the direction of detector sensitivity and its velocity vector. A term v/c arises because the detector sweeps out a column of the cosmic-ray plasma, another term 2v/c because the solid angle transformation increases the intensity in the direction of motion, and a term $(\gamma - 1)v/c$

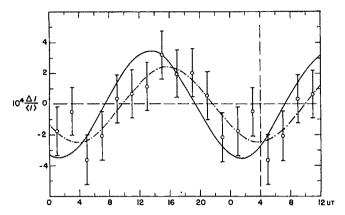

Fig. 1 Fractional muon intensity in 2-h intervals as a function of Universal Time. The dotted line is a two-parameter least-squares fit to the data; the solid curve is the *a priori* expectation due to the Earth's orbital motion. The error bars indicate a standard devation of $\sqrt{12/N_1}$, where a total of N_1 events were recorded.

because the Doppler shift of the energy spectrum changes the number of particles that exceed the detector's energy threshold. For a terrestrial detector at latitude λ sensitive to normally incident particles, and for $\gamma=2.75\pm0.03$ (ref. 2), the Earth's orbital velocity should lead to a diurnal amplitude modulation of $4.75\times10^{-4}\cos\lambda\cos^2{(i/2)}$, where i is the inclination of the Earth's axis. To first order in eccentricity there are no eccentricity effects. The effect should peak near dawn (06:00 LT), when the detector is sensitive in a direction most nearly parallel to that of the Earth's velocity.

The detector, located in a mine near Heber, Utah, was designed to measure the sidereal anisotropy of the cosmic-ray intensity, and is described in a report³ of the analysis of the first 3-yr data segment. Three layers of 100 plastic scintillators each were separated by concrete absorbers. The 25 × 154-cm counters were arranged in the north-south direction to optimize hourangle resolution. A detailed readout of triple-coincidence events permitted recognition of single muons at various angles. The muon threshold energy, as intensity-averaged over the topography, was 128 GeV. This energy corresponds to a median primary rigidity (momentum per unit charge) of 1,520 GeV/c (ref. 4), if 79% of the primaries are assumed to be protons. At this rigidity, the cyclotron radius of a particle at the Earth's orbit would be ~6 AU, and in interstellar space ($\mu \approx 2 \mu G$) about 170 AU, or 10⁻³ pc. Because of overburden details, the effective position of the detector was displaced 1.1° north of its actual position (to 41.7° N) and 9.3° east (to 110.8° W). As a consequence, 06:00 LT occurred at 13:24 Universal Time (UT), and at this latitude the expected fractional amplitude of the Compton-Getting effect should be 3.40×10^{-4} .

Data were recorded with an average muon trigger rate of 4.7 s⁻¹ between 4 January 1978 and 20 May 1983. The detector was operational 64% of the time; most of the down-time was the result of interrupted or ill-conditioned power. During this period 4.8×10⁸ muons were recorded in 60,500 half-hour summary records. After correcting for any dead channels⁵ and re-binning to correct for the hour-angle differences between different angular bins, the data were Fourier-analysed to search for spectral features near harmonics of (24 h)⁻¹. As a check, the data were also folded with sidereal and solar periods. Such 'folded light curves' agreed well with curves synthesized from the Fourier amplitudes. Figure 1 shows the results at the solar frequency. No evidence for solar harmonics higher than the first was found. Analysis of the sidereal frequency case will be published elsewhere.

Figure 1 also shows the *a priori* expectation discussed above (solid curve) and a two-parameter least-squares fit to the data (dash-dot curve). The least-squares fit has an amplitude of

 $2.47^{+0.72}_{-0.55} \times 10^{-4}$ and peaks at $15:42\pm1.0\,\mathrm{h}\,\mathrm{UT}$ (08:18 LT). The position-dependent amplitude is chosen from an off-centre Rayleigh distribution, as discussed in ref. 3. Quoted errors are such that the distance to the mean contains 34% of the area, in analogy to ±1 standard deviation (s.d.) errors for a normal distribution. The χ^2 for this fit is 3.8, which is unusually small for 9 degrees of freedom (d.f.). The probability of χ^2 being this small or less is $\sim8\%$. The data processing algorithms were tested for possible smoothing effects by processing Monte-Carlogenerated data with gaussian noise. As analysis of these data resulted in χ^2 s with expected values, we can only conclude that the low χ^2 observed with the real data is the result of a statistical fluctuation.

What other effects could confuse or mimic the Compton-Getting effect? Bending in solar magnetic fields should not be important at this rigidity, which was intentionally chosen to minimize such effects for the sidereal signal. The persistence of the sidereal signal reported in ref. 3 is evidence that this is the case. In addition, sidereal anisotropies have been reported at $500 \, \text{GeV/}c$ (refs 6, 7) and 1,000 $\, \text{GeV/}c$ (ref. 8), indicating that at even lower momenta the streaming direction in interstellar space is not lost in penetrating the Solar System. Even if directions were smeared by the solar fields, all that is required for observation of the diurnal Compton-Getting effect is that the cosmic-ray plasma moves with constant velocity in the Sun's rest frame.

According to detailed integrations by D. J. Cooke (personal communication), a normally incident 1,000-GeV/c proton at the Utah detector would have been deflected 1.2° to the east by the Earth's magnetic field. An analytical calculation with a simple dipole field model yields an effect which is slightly larger, but still negligible. However, this geomagnetic field might easily wash out the Compton-Getting effect at lower energies, where sensitivity to solar activity would also be expected.

Meteorological effects are more problematical. Most cosmicray muons come from meson decay in the upper atmosphere, at a mean height of ~200 mbar. Because the competition between interaction and decay is sensitive to air density, the muon intensity is greater when the stratosphere is warmer. More specifically, the fraction of pions with energy E_{π} which decay rather than interact at the mean production height is (1+ E_{π}/B_{π}), where the energy scale $B_{\pi} \approx 112 \text{ GeV}$ is proportional to temperature9. When kaons are included, the total temperature coefficient of $\Delta I/\langle I \rangle$ is $2.9 \times 10^{-3} \text{ K}^{-1}$. An effect as large as that expected from the Compton-Getting effect would thus occur if the diurnal temperature modulation of the upper atmosphere were as large as 0.1 °C; in fact, temperature effects larger than this are expected 10,11 . Similarly, a pressure coefficient of $-5.4 \times$ 10⁻⁵ mbar⁻¹ is expected, mostly because the increased muon range during a high-pressure period implies a higher energy threshold and therefore reduced intensity at the detector.

Meteorological effects have already received extensive attention ¹²⁻¹⁴, and we conclude that correlations between temperature and pressure in radiosonde data result in incorrect experimental coefficients¹⁵; that dominant pressure effects are not particularly correlated with the diurnal period and will thus tend to average out in a least-squares sense; and that radiosonde pre-flight setting errors of as much as ±1 K make detailed temperature corrections impossible. Our main evidence that temperature effects are small comes from the phase of the observed effect. A temperature-related maximum should occur several hours after solar noon, nearly out of phase with the observed effect. The amplitude reduction and slight phase lag which we observe is consistent with a temperature wave with amplitude 0.07 K and a maximum at 15:00 LT.

In principle, we might divide the data to simultaneously 'observe' two directions 90° apart, and by subtraction eliminate meteorological effects. In practice, most statistical significance is lost in the process. This approach has been used successfully at lower energies (where the counting rate is higher)¹⁶, but where

geomagnetic and solar effects are important.

The orbital motion Compton-Getting effect surely exists, and generations of cosmic-ray experiments have made corrections for it, and used evidence of some signal as evidence for freedom from solar modulation. At the same time, direct observation of the effect has been curiously rare. At 500 GeV/c, Davis and co-workers^{6,7} report consistency with the effect. Gombosi et al. 17 report it as below noise level in their air shower work at ~3× 10¹³ eV/c. The strongest evidence comes from a report by the Mt Norikura group 18, who report a 1.9-s.d. effect with the expected phase in their $\sim 10^{14} \text{ eV}/c$ air shower observations. The present results seem to represent the best confirmation to date of this classic effect.

This work was supported by NSF grant AST80-10727. The historical involvement of H. E. Bergeson, J. F. Davis, A. Larson, J. West and countless students is gratefully acknowledged.

Prospecting for planets in circumstellar dust: sifting the evidence from β Pictoris

David J. Diner & John F. Appleby

Earth and Space Science Division, Jet Propulsion Laboratory, California Institute of Technology, 4800 Oak Grove Drive, MS 183-301, Pasadena, California 91109, USA

Spectroscopic evidence for an extended gaseous shell around the A5V star β Pictoris has been available for more than a decade¹⁻⁵. Recently, the presence of a vast circumstellar cloud of particles was deduced from Infrared Astronomy Satellite (IRAS) measurements of excess thermal flux⁶⁻⁸. This interpretation is supported by a near-infrared (0.89 µm) coronagraphic image of the region beyond 100 AU from β Pic, which shows scattered starlight in a configuration consistent with a disk viewed nearly edge-on9. Conceivably, the β Pic system may represent one phase of planetary evolution. From an analysis of visible photometry and their coronagraph data, Smith and Terrile9 suggested that planetary accretion has swept out an extensive (~30 AU) clearing at the centre of the disk. We report here a new analysis of the same data and the results of including the IRAS observations in the analysis. The consequent models do not produce a large inner clearing and suggest alternatively that significant particle number densities occur within several AU of the star. An illustrative case is used to evaluate the short-wavelength detectibility of circumstellar disks in less favourable orientations than that surrounding β Pic.

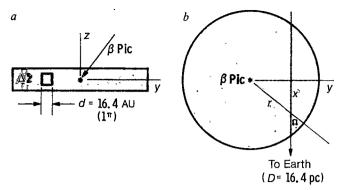

Fig. 1 Geometrical coordinates used in analysing the groundbased and IRAS observations of the disk orbiting β Pic. The disk is taken to be uniformly thick in the vertical direction and in an edge-on orientation as seen from Earth. a, Edge-on view; b, top

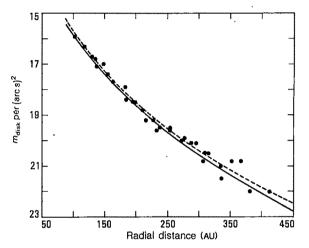

Fig. 2 Comparison of models for m_{disk} per $(\text{arc s})^2$ as a function of radial distance from β Pic (lines) with the observations of Smith and Terrile⁹ (filled circles). Dashed line, model derived from a fit to the coronagraph data only, assuming the modified gamma distribution for σ and g = 0.8. Solid line, model derived from a simultaneous fit to the coronagraph and IRAS measurements using g = 0.8 and $T_1 = 440$ K. Within the limits specified in the text, other choices for g and T_1 do not significantly affect the quality of the fit. The radial distribution parameters obtained for the models shown are $\eta = 0.15$, $\gamma = 0.50$ and $r_0 = 7.19$ AU for the 'coronagraph only' case and $\eta = 2.09$, $\gamma = 0.31$ and $r_0 = 0.03$ AU for the 'coronagraph + IRAS' case.

As a first step in modelling scattered light from the central star, it is appropriate to neglect attenuation of radiation traversing the disk and multiple-scattering effects. Thermal emission at 0.89 µm is justifiably ignored because the high radiating temperatures (for example, ~530 K at 200 AU) required to match the observed 0.89-µm brightness would make the disk brighter than the star at 2.2 µm, a wavelength at which no flux excess is observed8. In addition, because molecular scattering by the gaseous envelope of hydrogen inferred spectroscopically would require an H₂ abundance greatly exceeding the upper limit of $\sim 2M_{\oplus}$ (ref. 5; M_{\oplus} = mass of Earth), it is reasonable to interpret the observed features in the coronagraph data as starlight scattered by solid material. Integrating the scattering source function along the line of sight yields disk magnitude per (arcs)2 as a function of distance from the star:

$$m_{\rm disk}(y) \, \text{per (arc s)}^2$$

= $m_{\rm I} - 2.5 \log \frac{d^2}{4\pi} \int_{-\infty}^{\infty} \frac{\sigma[r(x, y)]}{x^2 + y^2} \, p[\Omega(x, y)] \, \mathrm{d}x$ (1)

Geometrical coordinates are shown in Fig. 1 and d = 16.4 AU

(1 arc s at the distance of β Pic from Earth), σ (AU⁻¹) is the radially varying scattering coefficient, p is the single-scattering phase function, assumed dependent only on the scattering angle Ω , and $m_{\rm I}$ is the I (0.89- μ m) magnitude of the star. We use $m_{\rm V}=3.85$ for the visual magnitude of β Pic¹⁰, and $m_{\rm V}-m_{\rm I}=0.23$ for an A5V star¹¹.

Smith and Terrile's analysis9 of the coronagraph data relied on several assumptions: an edge-on disk, a power-law distribution for the scattering coefficient (that is, $\sigma \propto r^{-\zeta}$) and isotropic scattering. In addition, because the absolute visual magnitude $M_{\rm V}$ of β Pic (2.78, based on a distance D of 16.4 pc) is 0.8 mag fainter than a typical A5 main-sequence star and 0.3 mag fainter than an A5 star on the zero-age main sequence (ZAMS)^{11,12}, they adopted a mean extinction of 0.5 mag relative to stars of the same type and luminosity class. This implies an optical depth of 0.46 in front of the star. Finally, because the power law is singular at the origin, they assumed $\sigma = 0$ for radial distances within an inner boundary whose location is governed by the adopted line-of-sight opacity in front of the star. From this analysis they concluded that the inner ~30 AU of the disk is relatively clear and that there is a fairly abrupt and substantial increase in disk opacity just outside the inner clear zone, beyond which σ decreases as the inverse cube of the radial distance. Under the assumption that the relative variation of σ is representative of changes in particle number density, a highly efficient mechanism must be invoked to explain the extensive clearing. As the inferred size of the clear region is of similar extent to our own Solar System, it is tempting to speculate that this paucity of material is the result of sweeping out by planetary accretion.

To test Smith and Terrile's model⁹ for uniqueness, we examined in detail several of their assumptions. First, we note that the inner clearing was artificially imposed a priori by the need to remove the singularity in the power law. To avoid this problem, we employed a continuous and bounded function for σ , namely, the modified gamma distribution¹³:

$$\sigma(r) = \sigma'(r/r_0)^{\eta} \exp\left[-(r/r_0)^{\gamma}\right] \tag{2}$$

The flexibility of this function allows for varying degrees of depletion at small r and rates of decay at large r. Second, instead of isotropic scattering, we used the Henyey-Greenstein phase function $p = (1 - g^2) (1 + g^2 - 2g \cos \Omega)^{-3/2}$ to represent more realistically the scattering by particulates¹⁴. In this expression, g is an asymmetry parameter equal to the average scattering angle cosine. Third, we examined all A5V stars in the Bright Star Catalogue¹⁰ with parallaxes >0.02 arcs (that is, within 50 pc, for which interstellar extinction is negligible). We find the cumulative mean and standard deviation of M_V for stars closer than 20, 30, 40 and 50 pc to be 3.45 ± 0.52 , 2.60 ± 0.81 , 2.53 ± 0.75 and 2.27 ± 0.73 , respectively, showing that the dispersion in M_V is comparable to or larger than the deviation of β Pic from the typical main-sequence and ZAMS values. Combined with the fact that the uncertainty of ± 2.9 pc in the distance to β Pic (D. Hoffleit, personal communication) corresponds to an additional 0.4 mag uncertainty in $M_{\rm V}$, we ascribe no statistical significance to the 0.5 mag extinction adopted by Smith and Terrile⁹. Noting furthermore that a correct assessment of the effect of disk opacity on $M_{\rm v}$ must include the scattering of light towards Earth in addition to attenuation of the direct stellar beam, we argue that the visible photometry does not provide a useful constraint on the optical properties of the disk. Instead, we included IRAS observations in our analysis.

The measured infrared magnitudes of β Pic are 2.66, 0.04, -2.75 and -3.41 at 12, 25, 60 and 100 μ m, respectively⁸. The magnitude scale is defined such that 0 mag at any wavelength corresponds to the flux from a black body at $T_{\rm ref}=10,000~{\rm K}$ radiating into a solid angle $S_{\rm ref}=1.57\times 10^{-16}$ ster. Using $T_*=8,500~{\rm K}$ as the effective temperature of an A5V star¹¹, we calculate the solid angle of β Pic from the K (2.2- μ m) magnitude⁸ of 3.47. The result implies $R_*/R_\odot=1.17$ (where R_* and R_\odot

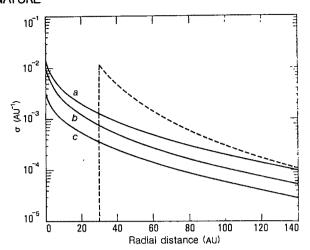

Fig. 3 Scattering coefficient σ at 0.89 μ m as a function of radial distance from β Pic, using the modified gamma distribution and fitting only the coronagraph data with several choices of g (a, 0.9; b, 0.8; c, 0.6). Smith and Terrile's model⁹, also derived using only their coronagraph data, is shown for comparison (dashed line) and predicts $\sigma = 1.17 \times 10^{-2} \, \mathrm{AU}^{-1}$ at 30 AU, no material inward of this distance, and an r^{-3} dependence beyond 30 AU. (These values are taken directly from ref. 9. We note, however, that use of Smith and Terrile's model assumptions and our equation (1) implies values of σ approximately a factor of five smaller.) Given the lack of direct near-infrared measurements within 100 AU, this figure demonstrates the sensitivity of the derived radial opacity distribution to the assumed functional form used to fit the data.

are, respectively, the radius of β Pic and that of the Sun). Because the IRAS fields of view are large relative to the disk dimensions implied by the coronagraph data, the measured infrared flux is equal to the sum of the stellar flux and the contribution from the entire disk. For an optically thin disk in which each element radiates isotropically, the orientation is immaterial and the simplest method of calculating the disk flux is to imagine a face-on rather than edge-on view. Letting B_{λ} denote the Planck function at wavelength λ , $T_{\rm d}$ the temperature of the disk at radius r, and Δz the vertical geometric thickness, and assuming for simplicity that the infrared absorption coefficient α is wavelength-independent at 12–100 μ m and follows the same radial distribution as the near-infrared scattering coefficient α (see equation (2)), we derive model infrared magnitudes

$$m_{\lambda} = -2.5 \log \left\{ \frac{\exp(c_2/\lambda T_{\text{ref}}) - 1}{D^2 S_{\text{ref}}} \left[\frac{\pi R_{*}^2}{\exp(c_2/\lambda T_{*}) - 1} + 2\pi r_0 \alpha' \Delta z \int_0^\infty \frac{(r/r_0)^{n+1} \exp[-(r/r_0)^{\gamma}] dr}{\exp[c_2/\lambda T_d(r)] - 1} \right] \right\}$$
(3)

where $c_2 = 1.43883$ cm K. Radiative equilibrium between the dust grains in the disk and the central star implies $T_d = T_1 r^{-1/2}$ (r in AU), where the temperature at 1 AU, T_1 , depends on the optical properties of the disk material.

The iterative method of nonlinear least-squares ¹⁵ was used to fit, first, the coronagraph data only and, second, the coronagraph and IRAS data simultaneously. At each iteration step, the 0.89- μ m solution was normalized to 19.5 mag (arc s)⁻² at 250 AU and the product $\alpha'\Delta z$ was determined by averaging the values required to match the 25- and 60- μ m observations. All integrals were evaluated numerically. Individual models were characterized by specifying values for the Henyey-Greenstein asymmetry parameter and the disk temperature at 1 AU. Due to the variety of mechanisms which promote removal of very small particles over long timescales, we assume grain sizes \geqslant visible wavelengths, in which case the limits ¹⁶ $0.6 \leqslant g \leqslant 0.9$ and the range ^{17,18} $200 \leqslant T_1 \leqslant 600$ K encompass a wide variety of particle

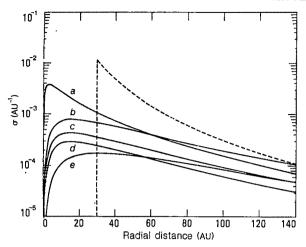

Fig. 4 Scattering coefficient σ at 0.89 μ m as a function of radial distance from β Pic, using the modified gamma distribution and fitting the coronagraph and IRAS data simultaneously for various choices of g and T_1 : a, $(g = 0.8, T_1 = 200 \text{ K})$; b, (0.9, 440); c (0.8, 440)440); d, (0.6, 440); e, (0.8, 600). The distribution at small radial distances is governed primarily by the IRAS results; note that a cooler disk requires larger opacity near the star to fit those data. Increased disk opacity is also required for higher values of g, to compensate for the decrease in amount of starlight scattered towards Earth. As an example of the magnitude of derived disk opacities, we use the case with g = 0.8 and $T_1 = 440$ K (model c) for illustration. We calculate a peak vertical (z-direction) infrared absorption optical depth of 1.5×10^{-3} , which occurs at 15 AU from the star in this model. The corresponding scattering opacity in the near-infrared depends on an assumed value for Δz : we compute in this case a peak vertical near-infrared scattering optical depth of 4.3×10^{-3} for each 10 AU of disk thickness. Note that in models a-e, significant disk opacity (50% of the peak value) is found within several AU of the star. Smith and Terrile's model⁹ is shown for comparison (dashed line).

sizes and complex refractive indices. The range for T_1 has been scaled from calculations performed for studies of the zodiacal cloud. Note that the value $T_1 = 440 \text{ K}$ is the equilibrium temperature for black-body grains.

The least-squares iteration was ended following negligible improvement in the sum of the squares of the residuals between the measurements and corresponding model magnitudes. Comparisons of our model 0.89-um magnitudes with the coronagraph data indicate excellent fits (see Fig. 2). When the IRAS data are excluded from the fitting procedure, the predicted infrared magnitudes, not surprisingly, do not match the IRAS data. For example, the model with g = 0.8 yields 12-, 25-, 60- and 100- μ m magnitudes of 0.80, -0.78, -2.28 and -2.89, respectively. Choosing $T_1 = 440 \text{ K}$ for illustration and including the IRAS data, these values become 2.55, -0.05, -2.66 and -3.66 mag. This is a satisfactory fit, especially in view of our simple assumptions. Thus, the introduction of further complexity into the modelling is not warranted until additional observations (such as spatially

resolved infrared data or coronagraphic images with greater radial coverage) become available. We note that the goodnessof-fit to the IRAS data is not particularly sensitive to g and that the warmer-disk models give better fits at 12-100 µm. The models which incorporate the IRAS data predict no flux excess at 2.2 µm and ~ 0.02 mag at 5 μ m.

The scattering coefficient at 0.89 µm derived by fitting the coronagraph data only is shown in Fig. 3 for several values of g. Figure 4 shows $\sigma(r)$ derived from simultaneous fits of the coronagraph and IRAS data for several combinations of g and T_1 . The Smith and Terrile model⁹ is reproduced in both figures. Note that for all of our models, significant opacity occurs well within the region which they inferred to be swept clear of material. Thus, these models indicate no sizeable inner clearing, particularly of the scale inferred by Smith and Terrile. It remains an open question whether planetary formation must be invoked to explain the distribution of disk material. Other mechanisms could account for a decrease in opacity close to the star, such as loss of particles due to radiative, electromagnetic or aerodynamic effects; or a change in particle properties such as a decrease in mean size.

One practical application of combined modelling of scattered and emitted radiation is in predicting the detectibility of randomly oriented circumstellar disks by coronagraphic imaging. The nearly edge-on orientation of the β Pic disk provides the most favourable condition for detection of scattered starlight. Taking m_{disk} per $(\text{arc s})^2 < 22$ as a reasonable ciriterion for detection (see Fig. 2) and using the case with g = 0.8 and $T_1 = 440$ K for illustration, we calculate that if the β Pic disk were in the less favourable face-on oreientation, it would be detectable by coronagraphic imaging at 100 AU from the star if its vertical geometric thickness (Δz) is greater than a few tenths of an AU and at 200 AU radial distance if $\Delta z \ge 4$ AU. IRAS has identified a number of stars with thermal infrared excesses, but with the exception of β Pic, attempts to obtain optical images of the material around those stars have, to our knowledge, not been successful.

In future, simultaneous acquisition of scattered-light and thermal infrared observations of stars with circumstellar shells or disks should be a promising method of determining the nature and distribution of orbiting material. Spatially resolved infrared observations, perhaps obtained interferometrically, combined with multi-spectral coronagraphic images with smaller occulting masks, would be very useful in characterizing circumstellar disk structure. The degrading effects of the terrestrial atmosphere probably dictate acquisition of such data from a spaceborne platform. Determination of the ubiquity of objects such as β Pic, evaluation of whether orientation of circumstellar disks is a critical factor governing their detectibility, and placement of such systems into the context of planetary evolution must await the collection and analysis of further infrared and coronagraphic observations.

Radio observations of PKS2314+03 during occultation by comet Halley

S. K. Alurkar, R. V. Bhonsle & A. K. Sharma

Physical Research Laboratory, Ahmedabad-380009, India

Strong interplanetary scintillations (IPS) were recorded at 103 MHz at Thaltej (23°02′ N, 72°36′ E) between 18 and 20 December 1985, when the quasar PKS2314+03 was occulted by the ion tail of comet Halley. The scintillation periodicities were near 1 s and their amplitudes decreased progressively as the source approached the end of the tail. The scintillating flux density on these days was 18.2, 11.4 and 4.7 Jy when the source was ~86° from the Sun. The r.m.s. density variations were 10, 6 and 3 electrons cm⁻³ on 18, 19 and 20 December respectively, and varied with distance r from cometary nucleus as $r^{-3.3}$. Assuming an ion velocity of 100 km s⁻¹, we show here that the observed periodicity of 1 s implies ion density inhomogeneities of the order of 100 km.

Comets develop ion or type I tails when they are 2-4 AU from the Sun¹. Plasma features such as kinks and knots seen in these tails are caused through interaction with the solar wind^{2,3}. Plasma density inhomogeneities in the solar wind scatter radio waves from a compact radio source and produce interplanetary scintillations that apparently broaden the radio source⁴. Attempts have been made to observe the angular broadening of radio sources as they were occulted by comet Arend-Roland⁵, and scintillations were observed during the occultation of radio source PKS2025-15 by comet Kohoutek⁶.

Regular observations of seven radio sources in the declination range +2° to +23° were made during December 1985 at Thaltej using a 10,000-m² correlation interferometer operating as a transit instrument at 103 MHz (ref. 7). Of these, six were scintillating sources. Sine and cosine outputs of the correlation receiver, together with a scintillometer⁸ output, were recorded

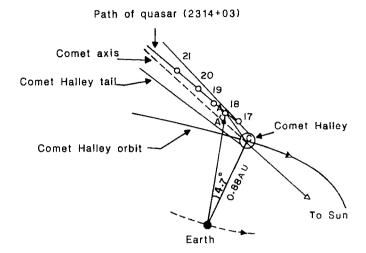

Fig. 1 Geometry, not to scale, of the occultation of PKS2314+03 (3C459) by comet Halley.

on a strip chart. These outputs, sampled 20 times per second, were recorded with time information on a digital magnetic tape. A real-time fast Fourier transform spectrum analyser (Model 512/S Rockland) can provide an average power spectrum of the scintillating source over a frequency range of 0.1-20 Hz.

Comet Halley was predicted to occult PKS2314+03 (or 3C459) during the period 17-21 December 1985. 3C459 is a scintillating source with \sim 70% of the total flux in the 0.45 arc s component⁹.

Figure 1 shows the geometry of the occultation for the period 17-21 December, for which the path of 3C459 as seen through the comet tail is indicated. The comet's position angle on 18 December was $\sim 66^{\circ}$, and the quasar on that day was 87.5° away from the Sun. Some relevant parameters of the occultation are summarized in Table 1. 3C459 has been observed since the

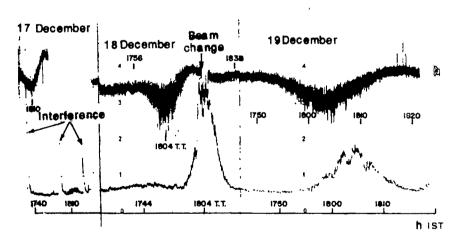

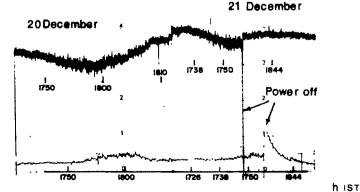

Fig. 2 103-MHz recordings of 3C459 during 17-21 December 1985. Top trace in each panel, sine receiver output; bottom trace, scintillometer output. Chart speed on 17 and 18 December was 5 and 10 cm h⁻¹, respectively, and 20 cm h⁻¹ thereafter. Note the strong scintillations on 18 and 19 December and weaker scintillations on 20 December.

beginning of December 1985, when it was $\sim 103^{\circ}$ from the Sun. Its average scintillating flux density was 3.5 Jy until 17 December, when the source was observed through the cometary tail at a distance of 0.08 AU from its nucleus.

On 18 December, however, as shown in Fig. 2, very intense scintillations were recorded when the distance from the comet nucleus to the point of intersection of the line of sight with the tail (AC in Fig. 1) was 0.12 AU. On 19 and 20 December the scintillations decreased progressively, when the corresponding distances were ~0.14 and 0.18 AU. Note that only sine and scintillometer outputs are shown in the recordings of Fig. 2, as the deflection due to 3C459 appears only on the sine response of the correlation receiver. On 21 December, when the source-comet distance was 0.2 AU, the scintillating flux density of 3C459 decreased to ~3.3 Jy.

Following the calibration procedure suggested by Duffett-Smith¹⁰ for estimating the mean source flux and the scintillating flux, IPS observations on 18-21 December, shown in Fig. 2, were analysed. The scintillometer outputs on these days correspond to r.m.s. scintillating flux densities of 18.2 ± 0.04 , 11.4 ± 0.04 , 4.7 ± 0.04 and 3.3 ± 0.04 Jy. Thus, the scintillation index, m (=r.m.s. scintillating flux/mean source flux) values become 0.42, 0.27, 0.11 and 0.08 respectively, for a mean source flux of 43 Jy.

Note that the average scintillating flux of 3C459 when it is $\sim 90^{\circ}$ away from the Sun is usually 3.5 Jy and reaches a maximum of ~ 12 Jy at 28-30°, when *m* begins to turn over at 103 MHz. Allowing for day-to-day maximum variations of 2-3 times 3.5 Jy, the measured scintillating flux values during the occultation by comet Halley are very significant.

The scintillation spectra (computed by the real-time spectrum analyser) obtained between 17 and 20 December are shown in Fig. 3. These were normalized with respect to the maximum value and are source spectra computed as the difference between 'on-source' and 'off-source' spectra, each averaged over 10 min. The spectra resemble typical IPS spectra¹¹, with a nearly flat low-frequency region below the spectral variations at \sim 0.2 Hz on 17 and 20 December, and at \sim 0.6 and 0.4 Hz on 18 and 19 December, respectively, when the scintillations were very strong. Auto-correlation analysis of the spectra gave average scintillation periodicities of 1.0 s.

The solar and ionospheric disturbances which might have caused these scintillations were studied using the data for the period 2-22 December 1985 (see ref. 12). Solar activity throughout this period was 'very low', while geomagnetic activity was 'quiet to unsettled', with no Sc-type magnetic storms. Furthermore, ionospheric beacon satellite data at very high frequency and ionograms at Ahmedabad did not indicate scintillation activity and spread-F respectively during this period.

An interplanetary transient or ionospheric scintillation causing the enhancement in scintillation of 3C459 was ruled out by studying IPS of 3C298, 3C318, 3C324, 3C368, 3C409 and 3C459, covering the declination range +2° to +23°, which were being regularly observed. Of these, 3C298 and 3C368 are within 8° declination of 3C459. Using many scintillating sources, Hewish et al. derived the shape and dynamics of large-scale interplanetary transients, which cover a typical solid angle of helio-

Table 1 Parameters of the occultation geometry Comet nucleus-Comet-Geocentric Solar Earthsource Date distance elongation (December along axis of comet of 2314+03 1985) (AU) (deg.) (AU) (deg.) 0.08 0.86 87.5 3.4 18 0.12 4.7 0.88 86.5 5.9 7.0 19 0.14 0.90 85.5 20 0.18 0.92 84.5 0.94 83.5 21 0.20

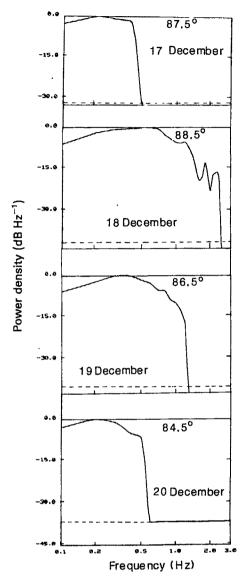

Fig. 3 Scintillation spectra of 3C459 on 17-20 December 1985. Dashed lines indicate noise level. Numbers in upper right-hand corners are solar elongations of 3C459.

longitude and latitude of $\pi/2$ sr. They also showed a strong correlation between enhancement in scintillation and total plasma density along the line of sight to a source. Except for 3C459, no other source showed enhanced scintillations during 18-20 December 1985, indicating that the enhancement was restricted to the direction of 3C459.

Thus, the strength of the observed scintillations in the direction of 3C459, and their progressive decrease from 18 to 21 December 1985 during the expected occultation of the source by comet Halley, strongly support our conclusion that the scintillations were caused by the scattering of the radio waves by density inhomogeneities in the ion tail of comet Halley.

The values of m on 18-21 December depend on the source-comet distance along the axis of the comet (A'C in Fig. 1), such that $m \propto r^{-3.3}$, where r in AU is the distance between the comet nucleus and A', the projection of A on the comet axis. For gaussian irregularities with weak scattering, and for a layer of thickness L containing density irregularities of scale size a, m is given by n4

$$m^2 = 2(\pi)^{1/2} r_a^2 \lambda^2 \langle \Delta N^2 \rangle aL$$

 λ is the wavelength of radiation passing through the scattering layer and r_e is the classical electron radius. In the case of comet

Halley, L is the thickness of its cylindrical ion tail, which is $\sim 10^5$ km (ref. 15).

The scintillation periodicities of 1 s imply scale sizes of density inhomogeneities in the cometary ion tail of 100 km (assuming their average velocity of 100 km s⁻¹ (ref. 16)), which compares well with scale sizes in the solar plasma estimated from IPS measurements17

Using the above formula, the average values of the r.m.s. density variations, $(\Delta N^2)^{1/2}$, in the ion tail are 10, 6 and 3 electrons cm⁻³ on 18, 19 and 20 December 1985, respectively. If the mean ion density in the tail of comet Halley is assumed to be 10^2 ions cm⁻³ (ref. 18) then $\Delta N = 10$ corresponds to 10% modulation of the mean density. This modulation is much higher than 4% for the solar wind at 0.1 AU.

Note that on 17 December 3C459 had just begun to be occulted by the comet Halley tail at a distance of ~0.08 AU from its nucleus. Average scintillations were observed on that day. This may be due to insufficient turbulence in that tail region. Also, ion density condensations in cometary tails cannot exist within 0.1 AU of the nucleus, due to the stabilizing effect of solar wind turbulence on the Kelvin-Helmholtz instabilities 16,19

The length of the plasma tail of comet Halley over which scintillations were observed up to 20 December was ~0.10 AU or 1.5×10^7 km, which is in good agreement with optical measurements15

We thank Professor S. P. Pandya for interest and the staff of Radio Astronomy and Ionospheric Groups for assistance. Discussions with Professors B. Buti and R. K. Varma were useful. We appreciate valuable suggestions by Dr P. J. Duffett-Smith of Cavendish Laboratory. Financial support for this work came from Departments of Space, Science & Technology, Government of India.

Imaging the outflow of ionospheric ions into the magnetosphere

Y. T. Chiu*, R. M. Robinson*, G. R. Swenson*, S. Chakrabarti† & D. S. Evans‡

* Space Sciences Laboratory, Lockheed Palo Alto Research Laboratories, Palo Alto, California 94304, USA

† Space Sciences Laboratory, University of California, Berkeley, California 94720, USA

‡ Space Environment Laboratory, National Oceanic and Atmospheric Administration, Boulder, Colorado 80303, USA

The discovery of ionospheric ion outflow into the magnetosphere has been considered a major advance in magnetospheric physics in the past decade. Satellite measurements in situ are, however, too localized to address the global scope of the phenomenon. It is therefore important to consider methods to image the global outflow of ionospheric ions into the magnetosphere. We consider below the concept and verification of imaging the global ionospheric outflow by using spectrophotometric observations of farultraviolet and extreme-ultraviolet solar lines resonantly scattered by ionospheric ions or exospheric neutrals in the auroral regions of the magnetosphere. We shall also present new satellite observations which verify the concept and show that this imaging capability is feasible with present technology.

Our concept of magnetospheric imagery proposed here originated with the interpretation of high-sensitivity, high-resolution observations of the solar 304-Å emission line intensity resonantly scattered by He⁺ in the plasmasphere. The observations were obtained by an extreme-ultraviolet telescope on the Apollo-Soyuz mission¹. The line intensities, measured while the instrument line of sight was spinning with the spacecraft, were shown to be in excellent agreement with line-of-sight He⁺ density distributions predicted by a kinetic equilibrium model of the plasmasphere2, when ionospheric densities measured simultaneously by the AE-C satellite at 300 km altitude were used as boundary conditions of the model. The success of this experiment and interpretation suggests that an image in line emissions resonantly scattered by magnetospheric ions of ionospheric origin or exospheric neutrals may similarly be converted into

an image of their density distribution in the magnetosphere. Furthermore, if spectrometric information is available, the flow speed and temperature of the ions or neutrals can be derived, so that an image of the ionospheric ion outflow into the magnetosphere in the high-latitude region can be made. (For reviews of various aspects of the ion outflow phenomenon, see refs 3-6.)

The generalization of concepts stemming from the earlier He II 304-Å work¹ requires a search for other emission lines, because the high-latitude ion outflows consist primarily of O and H⁺, as well as some He⁺ in the polar cap. We have determined that the solar O II 834-Å line can be used analogously to the He II 304-Å line to determine O+ distributions and outflow. The proton has no resonant scattering lines; however, outflowing hot H+ can charge-exchange with cold exospheric neutral atoms to produce hot outflowing H⁰ which can, in turn, resonantly scatter Doppler-shifted Ly- α from the Sun. Thus, the same principle can be applied to Doppler-shifted Ly- α observations to determine the hot H⁰ distribution. We show that our concept is workable, in principle, and is verifiable with current observations, although there is no imaging capability in currently available instruments. Details of data deconvolution will not be considered.

As both the He⁺ and O⁺ lines can be treated analogously, we discuss these two together. Figure 1 summarizes the results of observation and interpretation of the He⁺ line in the plasmasphere.

For the He⁺ and O⁺ lines in the auroral region, there are two important sources of illumination: (1) solar line emission, F_s , and (2) auroral line emission, $F_{\rm a}$, excited at ~100 km altitude by electron impact. The solar flux F_s is uniform but, as the auroral source is close to the region of resonant scattering, the geometric properties of F_a need to be included. The resonantly scattered O II 834-Å and He II 304-Å line intensities, I, seen above ~600 km altitude can be considered optically thin, especially as the auroral ionosphere is particularly tenuous. Thus, the intensity is given by

$$I = \int dL (F_s + F_a) \sigma_{rs} N_i(L)$$
 (1)

where σ_{rs} is the resonance scattering cross-section (=2.6× 10^{-13} cm² for the 834 Å line) and $N_i(L)$ is the ion density along the line of sight, L. This equation allows us to derive the

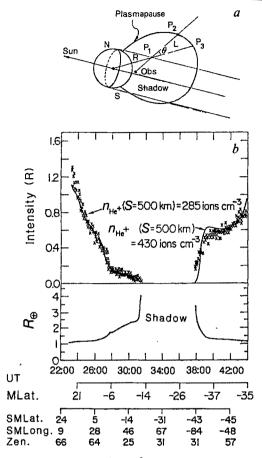

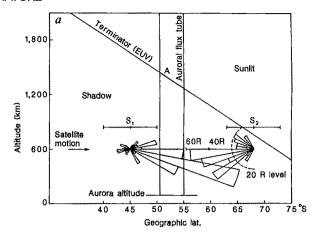

Fig. 1 Intensity of the He⁺ 304-Å line measured in a spin-scan of the Apollo-Soyuz photometer. The viewing geometry is shown in a. The satellite (OBS) measures the line intensity from the sunlit portion of the line of sight (L) between P₁ and P₂. The altitude (R₁) of the point P₁ which is the intercept of L with the terminator, is shown in b. The magnetic latitude of P₁ (MLAT), the satellite magnetic coordinates (SMLat., SMLong.) and the zenith angle of the line of sight (Zen.) are also shown. The agreement between the model (solid lines) and the data (crosses) demonstrates the capability of deriving the density distribution of He⁺ in the plasmasphere by imaging the 304-Å line intensity.

appropriate ion density distribution with the help of a theoretical profile superimposed on the viewing geometry shown in Fig. 1. The pecularities of the Earth's shadowing impose tomographic signatures (note the kinks in the line intensity profile) in much the same way as lead is used in X-ray tomography in the laboratory. A unique set of density model parameters can be determined.

We have been able to test this concept with the O II 834-Å line by using data from the University of California Berkeley extreme-ultraviolet spectrometer flown on board the P78-1 satellite. The P78-1 satellite was placed in a 600-km-altitude circular orbit, with an inclination of 97.7° and an orbital period of 96 min. The orbit is Sun-synchronous, precessing at 1° per day, with the spacecraft orbit lying essentially in the noon-midnight plane. The spectrometer is housed in the spinning wheel of the spacecraft, with the spin axis of the wheel perpendicular to the orbital plane. The spectrometer's line of sight is oriented 120° from the spin axis, and, as the wheel rotates at 11 r.p.m., the instrument line of sight sweeps out a cone, alternately viewing Earth and space, never looking closer than 30° to the Sun.

To test the magnetospheric O^+ imaging model, we have chosen a pass where a night-time aurora was observed by the instrument over the South Pole on 22 March 1979. The down-looking intensity profile of the O^+ 834-Å feature as a function of latitude indicates an auroral arc at ~45,000 s UT, centred between -50°

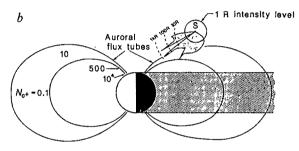

Fig. 2 a, Intensities of the O^+ 834-Å line as a function of the angle between the zenith and the line-of-sight direction of the extreme-ultraviolet (EUV) spectrometer aboard the satellite P78-1. Spin-angle intensity profiles accumulated during the intervals centred at S1 and S2 are shown. Wavelength-independent background has been subtracted. The location and extent of the auroral flux tube are determined by the measured zenith and nadir intensities. Note that the 834-Å source volumes are at altitudes as high as 2,000 km. b, Simulated O^+ 834-Å line intensity profile seen by a hypothetical satellite S at $4R_{\rm E}$ is shown on the nightside lobe of an auroral flux tube. The input O^+ density profile 9 as a function of distance along the field line is shown on the dayside lobe of the flux tube. Instrument sensitivity of 1 R is needed to image the distribution of O^+ on the entire auroral flux tube.

and -55° geographic latitude. Figure 2a shows spin-scan profiles of the O+ 834-A line accumulated for ~150 s, centred at two satellite locations S1 and S2 along the satellite path towards the South Pole, plotted as linear polar bar graphs according to the directions of the zenith-angle bins. The satellite was in the Earth's shadow at both points, viewing the auroral region forward from S1 and then backward from S2. From the forwardbackward anisotropy of the intensity pattern, it is clear that the instrument is viewing emissions from the auroral flux tube and that this is the predominant emission source at such high altitudes. The up-looking intensities of 1-20 R are of particular interest because they correspond to sources located at altitudes as high as 2,000 km. Using the model parameters of $N(O^+) \simeq$ 500 cm⁻³ at 2,000 km over a typical evening discrete-auroral-arc region of width ~200 km lit by solar and auroral 834-Å emissions, we found, for example, that the model predicts a luminosity of 6 R, in agreement with the up-looking intensities at S2, which include the sunlit and aurora-lit regions of the flux tube at 2,000 km. The extreme-ultraviolet background has been corrected for in the data and the 834-Å signal, though weak, stands out well above background.

The data clearly show that the auroral flux tube up to ~2,000 km can be imaged with an extreme-ultraviolet instrument at 834 Å. The intensity observed is in agreement with that expected from auroral flux tube models⁹. This verification allows

us to simulate what we may expect from the O⁺ line when viewed from a high-altitude platform. We have run a model of electric field and plasma distributions⁹ for a discrete arc with a total potential drop of 1 keV and O⁺ density of 500 cm⁻³ and H⁺ density of 70 cm⁻³ at 2,000 km, to simulate an average auroral flux tube. These densities are consistent with ISIS-2 observations¹⁰. The O⁺ densitites are shown at roughly appropriate locations on the sunlit auroral lobe in Fig. 2b. The solar flux is assumed to be 1.3 kR, and the auroral flux is ~1 kR (ref. 11) at ~100 km altitude. With such a model, one can simulate the expected intensity of the 834-Å resonance scattering line seen at any viewing geometry. Such a simulated intensity plot for the 834-Å line is shown on the nightside lobe of Fig. 2b, in which the intensity of a 360° spin-scan is shown as the mottled area centred around a hypothetical satellite, S, at $4 R_E$ (where R_E is the radius of the Earth). It is seen that instrument sensitivity to 1R is required to obtain a deconvolution of O⁺density distribution of the auroral flux tube to \sim 5 $R_{\rm E}$. The simulation is for the minimum outflow of an inverted V. Other sources of O+ outflow, such as conics and polar wind, add to the 834-Å intensity. Note that the simulation applies only to 834-Å emission of O+ accelerated upward by the inverted V. Such emissions have distinct Doppler shifts and broadenings. When the instrument is looking in the downward direction, the line core will be cluttered with 834-Å dayglow¹² (~0.5 kR) and nightglow¹³ (~1 R). These issues of background require high-resolution spectrometry, but we cannot address these issues here.

If our concept of magnetospheric imagery is valid, it would imply that solar Ly- α emissions should also be resonantly scattered by the hot H⁰ outflow created by charge-exchange interaction between the H⁺ outflow and neutral constituents of the exosphere. Such emissions are clearly distinguishable from the intense geocoronal background because such hot H⁰ will resonantly scatter solar Ly- α at Doppler-shifted wavelengths from the cold geocoronal line core. Note that the geocoronal Ly- α width corresponds to an exospheric temperature of ~1,000 K (~0.1 eV) for the cold H⁰; therefore, any H⁰ with higher energy is defined as hot for the present purposes. Our concept predicts the existence of a hot Ly- α emission source at the auroral magnetospheric flux tubes.

Evidence of such a hot emission source in the magnetosphere was obtained by the spectrophotometer flown on Spacelab 1. The instrument was equipped with an absorber specifically to eliminate the geocoronal Ly- α line core so as to study hot emission sources14 which are Doppler-shifted and/or broadened to the geocoronal line wings. An unexplained magnetospheric source of hot emissions with an intensity of ~200 R, after subtraction of interplanetary background, and ~20° wide in orbital angle was detected by the instrument¹⁴ at ~22:54 UT on day 341 of 1983. The viewing geometry projected onto the horizontal plane is illustrated in Fig. 3, showing the Spacelab 1 ground track at southern high latitudes. The hot emission source was observed in the zenith direction, perpendicular to the ground track and out of the plane of the figure. Within a few minutes of the event, the NOAA-7 satellite flew through the southern auroral region and the NOAA-8 satellite flew through the northern auroral region. Both detected auroral electrons in the vicinity of -65° to -70° geomagnetic latitudes, but virtually no protons above the instrument threshold were found. Assuming conjugacy, these two NOAA satellite observations approximately defined the low-altitude aurora as shown on Fig. 3. The hot emission source is clearly not from the direction of the low altitude aurora, whose intensity in Ly- α is usually \sim 6 kR and is emitted by the cold geocoronal H⁰. We conjecture that the hot emission of ~200 R originates from Dopper-shifted Lyα resonance scattering of solar emissions by the hot H⁰ which are produced by charge exchange between outflowing hot H+ and cold exospheric neutral atoms at several thousand kilometres up the auroral flux tube. If so, the source region is bounded below by the intercept of the equatorward edge of the auroral

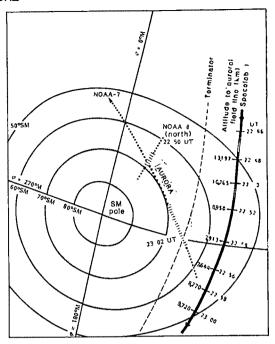

Fig. 3 Viewing geometry of Spacelab 1 observation 14 of an unaccounted-for Ly-α emission source in the magnetosphere. The source was observed between 22:50 and 22:57 UT, near the zenith direction.

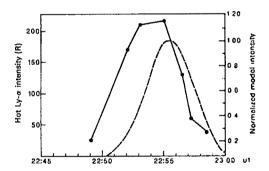

Fig. 4 Comparison of the observed hot Ly- α intensity profile (solid curve) with the expected model profile (dashed curve). The model curve is normalized to unity at 22:56 UT, when Spacelab 1 is at closest approach to the equatorward boundary of the auroral flux tube in the zenith direction. The model assumes that the unknown hot Ly- α source is the hot H^o produced by charge exchange between hot outflowing H⁺ and exospheric neutrals.

flux tube with the line of sight of the instrument. The altitudes of these equatorward intercepts are shown along the Spacelab 1 ground track on Fig. 3. Note that the closest approach of these equatorward intercepts to the instrument occurs near the observed hot emission source. This intercept is important in understanding why the source is highly localized.

To consider the source localization, we note that the intensity, I, of the hot emission can be written approximately in terms of the solar flux F_s ($\sim 250 \text{ kR}$)¹⁵, the resonance scattering cross-section σ_{rs} ($\sim 2.5 \times 10^{-13} \text{ cm}^2$) and the hot hydrogen density N_H

$$I \simeq F_{\rm s} \sigma_{\rm rs} \int_{z_{\rm r}}^{z_{\rm p}} \mathrm{d}z \, N_{\rm H}(z) \tag{2}$$

where z_e is the altitude of the equatorward intercept and z_p is the altitude of the poleward intercept of the line of sight with the auroral flux tube. Locally, the density of hot H^0 can be parameterized in terms of a scale height h along the field line

$$N_{\rm H} = N_o \exp -[(z - z_o)/h \sin \lambda] \tag{3}$$

where N_0 is the density at the reference altitude z_0 along the

field line at invariant latitude λ . For our case, z_p is much larger than z_e because the auroral field lines are approximately radial, yielding

$$I = F_s \sigma_{rs} h \sin \lambda N_o \exp -[(z_e - z_o)/h \sin \lambda]$$
 (4)

Thus, the intensity is expected to be an exponential function of the equatorward intercept z_e , and the width of the emission source is expected to be determined by the projected scale height $h \sin \lambda$.

Figure 5 shows the comparison between a modelling of the intensity according to equation (4) and the actual observations along the satellite ground track. The observed width is well fit with a scale height of ~1,000 km and, indeed, the intensity varies approximately with the equatorward intercept as an inverse exponential. The observed intensity is obtained by subtracting the fitted interplanetary hot emission background¹³ from the total hot emission to obtain the magnetospheric component of the hot emisson intensity. Even without assuming any longitudinal variations of the aurora, the two intensity curves shown in Fig. 4 are sufficiently similar in shape and location to support our conjecture and to explain the most significant feature that the magnetospheric hot emission source appears to be localized. Furthermore, using the peak intensity of ~200 R and the fitted

width of ~1,000 km, we can determine from equation (4) that the hot hydrogen source density is $\sim 30 \text{ cm}^{-3}$. This number density is quite reasonable, as the hot H⁰ includes all populations above ~ 0.1 eV.

We thank J. L. Bertaux for providing information on the Spacelab 1 observations.

Periodicity of the Earth's magnetic reversals

Richard B. Stothers

National Aeronautics and Space Administration, Goddard Space Flight Center, Institute for Space Studies, 2880 Broadway, New York New York 10025, USA

Reversals of the Earth's magnetic field may occur with a certain regularity. Using observed percentages of normal and reversed polarity during different time intervals, Negi and Tiwari¹ detected several significant periodicities, notably one of 32-34 Myr. Raup² used the dates of individual reversals to propose a 30-Myr period in the frequency of reversals, although Mazaud et al.3 obtained a periodicity of only 15 Myr. Like Negi and Tiwari's other detected short periods, the 15-Myr period may be harmonically related to a basic 30-Myr period⁴. It has also been suggested that these are accidental periodicities arising in a short record^{5,6}, or are harmonics of the record length itself7. In fact, all of the cited studies have used different data, different record lengths and different methods of time-series analysis. Raup8 has consequently retracted his original claim. Here I present a much fuller analyis of the reversal record and show that a statistically significant period of ~30 Myr does formally exist, in spite of the cited differences.

For consistency with the most recent studies, most of the calculations reported here have used the dates given by Harland et al.9 for 296 magnetic reversals in the past 165 Myr. Raup² and Lutz⁷ displayed histograms of these dates in bins with widths of 5 and 8.27 Myr, respectively. Because 5 Myr is a harmonic of the suggested 30-Myr period, and 8.27 Myr is too long to reveal visually a 30-Myr period, an unbiased bin width of 4 Myr is used here to construct a new histogram, shown in Fig. 1. Inspection suggests that peaking of the magnetic reversal rate near both ends of the record will produce a very strong artificial periodicity of ~140 Myr, while the complete absence of magnetic reversals near the middle of the record (Cretaceous quiet interval) will create a strong first harmonic of ~70 Myr. Superimposed on the bowl-shaped histogram, however, there appears to be a possibly real oscillation of minor peaks with a period of ~30 Myr. Other published displays of the reversal frequency suggest a shorter wavelength of 15 or 20 Myr (refs 3, 10), but only the 30-Myr oscillation appears when the data are binned

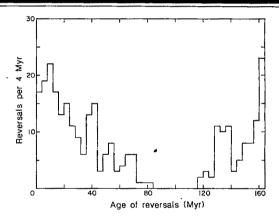

Fig. 1 Magnetic reversal frequencies shown in bins of width 4 Myr (data from ref. 9). Note the minor peaks spaced at ~30-Myr intervals.

in very short intervals, such as 1 Myr.

To proceed further, the dates of individual magnetic reversals may be analysed by using a technique in which the observed dates t_i $(i=1,2,\ldots,N)$ are fitted to a linear periodic function of the type $t = t_0 + nP$, where P is a trial period, t_0 is a trial value for the most recent epoch, and n is an integer. In the original formulation of the technique¹¹, I minimized $N\sigma^2$, the sum of the squares of the residuals for each trial epoch, to obtain a best fit for a selected trial period, and computed a 'residuals index' $(\sigma - \sigma_c)/P$, where $\sigma_c/P = [(N^2 - 1)/12N^2]^{1/2}$. Raup and Sepkoski¹², in independent work, searched for the arithmetic mean of the residuals that was closest to zero, and Lutz⁷ made a circular transformation to obtain phases of the observed data, the dispersion of which was then minimized by performing two trigonometric summations, as in Fourier analysis. Lutz's variation of the method allows a correction to be made for the unequal weighting of the dates which biases most, if not all, time-series analyses. However, as he showed that this effect is very small for the present data, I neglect it here and use the technique as originally formulated. Earlier versions, for both temporal¹³ and spatial¹⁴ problems, looked for either a leastsquares or maximum-likelihood solution for two unknowns and so did not compute the spectral information, or else assumed a known value for the most recent epoch.

The computed spectrum of the residuals index for the adopted dates of magnetic reversals (Fig. 2) displays many periodicities.

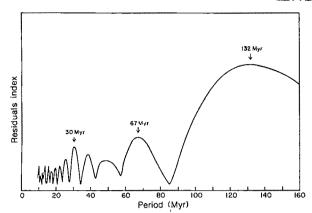

Fig. 2 Spectrum of residuals index for the complete time series of magnetic reversals, t = 0-165 Myr. The residuals index measures the goodness-of-fit of the observed times series to an assumed, perfectly periodic time series.

To determine their robustness, the record can be progressively truncated: successive cuts of 5 Myr are applied from the present time to as far back as 65 Myr ago (beginning of the Cenozoic Era). Table 1 lists the periods of all spectral peaks appearing at trial periods $P \ge 10$ Myr. A number of important features of this table should be noted. First, the longest period is always of the order of the length of the truncated record. (This period always has the highest spectral peak.) Second, the next-longest period is always nearly equal to one-half of the longest period. (This first-harmonic period has the next-highest spectral peak if the amount of truncation is <25 Myr.) Third, the dominant period occurring elsewhere in the computed spectra is 28-33 Myr. Its precise value oscillates down Table 1 in a discontinuous, saw-tooth fashion with a wavelength of ~30 Myr. The same wavelength of oscillation (with a slight phase shift) characterizes the neighbouring periods of 22-25 and 20-22 Myr, although the shorter periods of 18-19, 17-18 and 15-16 Myr vary down the table with a wavelength only half as large. Note that the percentage by which the period varies is smaller for the shorter periods, so that the variations of the four shortest periods, 13, 12, 11 and 10 Myr, are imperceptible. Thus, the more cycles a record contains, the less these cycles will be distorted by the record length.

The average values of the 12 periods that lie in the range 10-58 Myr are closely represented by the individual periods shown in the first row of Table 1, and are very close to what would be expected for an ideal time series consisting of six dates successively separated by 30.1 Myr. An explicit comparison of observed and expected periods is presented in Table 2, including a simple harmonic interpretation¹¹. The correlation coefficient between the 11 pairs of observed and expected periods (excluding the generating period of 30.1 Myr) is r = 0.997. The significance of this value has been tested by correlating the sequence of 11 observed periods with 5,000 simulated sequences, each consisting of 11 numbers drawn at random from the range 10-58 Myr and then ordered. Fewer than 0.1% of the simulated sequences showed $r \ge 0.997$. Since there is no a priori reason to expect precisely 11 periods to show up in the range 10-58 Myr. this represents a very conservative test of significance.

An independent test has been made by generating 5,000 artificial time series, each containing 296 dates selected randomly from the time interval 0-165 Myr and then ordered. The spectrum of the residuals index has been computed for each time series and compared with Fig. 2. Fewer than 0.1% of the synthetic spectra showed a residuals index at P=30 Myr that was higher than the observed peak. However, this test assumes 30 Myr as an a priori period and does not take into account the non-stationarities in the observed time series, as illustrated in Fig. 1.

Raup² performed a different significance test by randomizing the order of the observed time intervals. He found a low percentage (0.6%) of simulated cases in which the height of the observed spectral peak at $P = 30 \,\mathrm{Myr}$ was surpassed. Lutz detected the statistical significance of the observed peaks at shorter periods, but did not recognize their harmonic connection to the 30-Myr period. Instead, he associated these periods with the record length, an interpretation that was based on a limited truncation back to only 21 Myr BP. Additional evidence against Lutz's interpretation follows from an attempt to match the provisionally expected series of harmonics (1/2, 1/3, 1/4,...) of the longest period in each row of Table 1 to the rest of the observed periods along the same row. Discrepancies of up to 15% in the values of the observed periods occur, and not all of the observed periods can be successfully identified. The number of extraneous periods per row is three in one of the rows, two in six rows, and one in another six rows; only one row has no extraneous period at all.

Truncation of the record in the middle of the Cretaceous quiet interval provides a further test. Separate spectral analyses of the more recent time segment (t = 0-83 Myr, N = 196 dates) and the older time segment (t = 118-165 Myr, N = 100 dates) yield the following results for trial periods in the range 10-40 Myr. The more recent time segment contains five spectral peaks at periods of 32.7, 20.0, 15.9, 13.3 and 9.8 Myr; the older time segment contains three peaks at 29.9, 14.2 and 10.4 Myr. For comparison, two ideal time series consisting of three dates and two dates, respectively, with generating periods of 32.7 Myr and 29.9 Myr,

^{*} Highest spectral peak for periods <58 Myr.

show high peaks only at 32.7, 21.8, 16.3, 13.1 and 10.9 Myr and only at 29.9, 14.9 and 10.0 Myr. The corresponding harmonic identifications are 1, 2/3, 1/2, 2/5 and 1/3, and 1, 1/2 and 1/3.

Several conclusions can be drawn from this comparison. One is that the 15-Myr period detected by Mazaud et al.3 in the more recent time segment is probably just a harmonic period, rather than the basic period. Although progressive truncation of this segment of the record back to 35 Myr BP leads, in some cases, to the highest spectral peak being at P = 13-15 Myr, comparison with the computed spectra of the corresponding ideal time series shows unambiguously that the generating period remains P =30 Myr (plus or minus the amount of period oscillation). Second, the presence of the 30-Myr period in the separate spectral analyses for t = 0-83 Myr and t = 118-165 Myr demonstrates that this periodicity is not being produced by the 35-Myr quiet interval. (Raup² came to the same conclusion.) Third, the abrupt shifts in the number of observed periods, going down Table 1, arise from the change in the number of cycles covered as the record is progressively truncated. For an ideal time series, the total number of integer multiples of harmonics that appear in

^{*} Very low spectral peak.

the computed spectrum is by definition controlled by the value of the largest-occurring integer, which turns out to be equal to the number of cycles covered by the time series.

Three additional checks have been made of the above results. First, Fourier analysis has been applied to the histogram shown in Fig. 1. Spectral peaks were determined to occur with relative heights and absolute periods that agreed, within the resolution of the method, with the peaks found by linear analysis. To examine the effect of the obvious non-stationarities in Fig. 1, de-trending was performed by subtracting the strongest contributing Fourier components. Accordingly, the two longest cycles, corresponding to the 132-Myr and 67-Myr periods of Fig. 2, were successively removed. Fourier analysis of the residual data then showed the highest spectral peak occurring at 30.9 Myr, which was shifted only slightly from the original value of 30.4 Myr. A similar Fourier analysis of Raup's² and Lutz's⁷ histograms, as well as of a histogram with a 1-Myr bin width, yielded essentially identical results. This check shows that the method of analysis does not bias the results.

A second test concerned the possible influence of undetected magnetic reversals. If the unknown reversals are distributed randomly or proportionally among the known ones, their omission should not significantly affect the present results. To simulate their omission, the known magnetic reversals were systematically pruned from the record. Only the recent time segment t = 0-83 Myr was considered, and all fixed-polarity chrons of less than a certain length δt were excluded from the data set. As the missing chrons from the original record are probably shorter than 0.04 Myr (ref. 10), a very conservative test uses $\delta t \gg 0.04$ Myr. When $\delta t = 0.5$ Myr is used, the basic period of 30.1 Myr still emerges (N = 49 dates). Even with $\delta t =$ 1 Myr, the period remains 28.9 Myr (N = 19 dates).

A third check of the present results involved using two different sets of magnetic-reversal dates: those of Kent and Gradstein¹⁵ (t = 0-169 Myr, N = 283 dates) and of Lowrie and

Table 3 Summary of results for the basic period (P) and phase (t_0) of magnetic reversals

^{*} Average of the truncation results.

Alvarez¹⁶ (t = 0-84 Myr, N = 174 dates). Analysis of these dates by the linear technique produced the results shown in Table 3. In view of the small number of cycles covered, the differences seem rather minor, the total spread among the periods being ±3 Myr. Using maximum-entropy analysis, Pal and Creer¹⁷ independently found the 32.1-Myr period in the data of ref. 16.

The above results suggest that a real periodicity exists in the record of magnetic reversals, supporting the claims of Negi and Tiwari¹ and of Raup². With fine tuning of the truncated-record results, the mean value of the basic period falls at 30.5 Myr (ref. 9 data) or 29.5 Myr (ref. 15 data). Shuter and Klatt's 18 136-Myr period is now seen to arise only from the record length. Like the basic period, the phase oscillates in a discontinuous: saw-tooth fashion with progressive truncation, and returns to its starting value every ~30 Myr. A best estimate of its mean value is $t_0 = 10 \pm 8$ Myr BP (ref. 9 data) or $t_0 = 7 \pm 8$ Myr BP (ref. 15 data). Note that t_0 represents the most recent epoch of the mean cycle and therefore is not necessarily equal to the most recent time of high magnetic-reversal frequency, unless the times are strictly periodic.

These results do not prove that there is a physical periodicity in the Earth's magnetic record, nor do they prove that any periodicity, real or accidental, is strictly regular. However, the already demonstrated^{4,19} coincidences in time between a high rate of magnetic reversals, heightened global tectonic activity, and impact cratering do at least suggest that periodic or episodic large-body impacts may trigger many of these disturbances.

Thermohaline intrusions created isopycnically at oceanic fronts are inclined to isopycnals

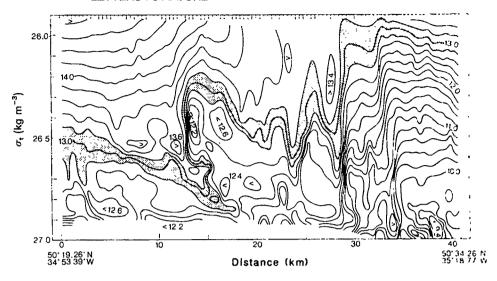

J. D. Woods*, R. Onken & J. Fischer

Institut für Meereskunde an der Universität Kiel, FRG

Thermohaline intrusions have often been observed extending several kilometres from ocean fronts1. They have a central role in models of mixing^{2,3}; however, their origin has been the subject of controversy. Laboratory studies led to the idea that intrusions might be formed by double diffusion⁴⁻⁶, in which case they would slope across isopycnals (surface of constant density). That signature has been identified in ocean fine-structure sections7. Observations of the three-dimensional structure of meandering fronts led to a different conjecture: that intrusions might be formed isopycnically by the ageostrophic circulation within unstable meanders on the frontal jet 1,8. In that conceptual model, double diffusion

^{*} Present address: NERC, Polaris House, North Star Ave, Swindon, Wiltshire SN2 1EU, UK.

Fig. 1 Density variation (σ_t) of isotherms in a vertical section across the North Atlantic polar front, surveyed with the Kiel Sea Rover apparatus in summer 1981. The horizontal resolution (400 m) is indicated by the tick marks on the upper axis; the vertical depth range lies between 30 and 80 m. The temperature range between the 12.8 °C and 13.2 °C isotherms is shaded.

does not initiate intrusions, but may extend and dissipate those created by frontal circulation. Here we present first the observed structure of such an intrusion and then the results of a dynamical model simulating the isopycnic generation mechanism at an unstable meandering front. We show that thermohaline intrusions formed isopycnically also slope across density surfaces, so there is no need to invoke double diffusion to explain such structures.

We have observed a thermohaline intrusion at a meander structure of the North Atlantic polar front. The section presented here (Fig. 1) was obtained by the Kiel Sea Rover towed CTD (conductivity/temperature/depth) system¹⁰. It represents a high-resolution snapshot of a thermohaline front in the seasonal pycnocline. The orientation of the section was almost perpendicular to the front which separates the warm and saline water in the anticyclonic meander-ridge, from the cold and fresh water in the cyclonic trough of the meander. Isopycnic analysis eliminated internal wave noise¹¹. The resulting product revealed strong thermohaline fine structure created by the three-dimensional frontal dynamics.

The 13 °C isotherm is folded in the vicinity of the major thermoclinicity signal. Relatively warm water is intruded into a region of cooler and fresher water, with the axis of the intrusion being clearly inclined to isopycnic surfaces. The horizontal extent of the fold was \sim 6 km and the vertical scale of the intrusion, estimated from the mean static stability profile, was \sim 10 m.

We modelled the development of a meandering front in two stages: (1) frontogenesis, which transforms the initial (largescale) baroclinicity and thermoclinicity into a jet with an associated T-S (temperature-salinity) front, and (2) instability of the jet. It is important that the initial condition for stage (2) is the output of stage (1), so that we can establish the sensitivity of intrusion structure to large-scale initial conditions. Our simulation of thermohaline intrusions was based on a primitive equation model with quasi-isopycnic coordinates¹². The first stage, describing frontogensis in two dimensions, was an extension of that described in ref. 9, with initial thermoclinicity described by horizontal isotherms. It gave the frontal structure shown in Fig. 2a. That was used as the initial conditions for the second stage¹³, a channel model based on the Bleck-Boudra quasi-isopycnic coordinate scheme¹², rigid side walls with free slip, and cyclic downstream boundary conditions. The grid has 10 isopycnic layers, each with a rectangular array of 32×64 grid points, spaced 2.5 km apart in the cross-stream direction and in the downstream direction. Meanders grow in response to an initial small perturbation in the stream function. In the present examples, the disturbance had downstream amplitude as shown by the streamlines at a depth of 25 m after 40 days of integration (Fig. 3a). The corresponding pattern of isotherms on an isopycnic surface (Fig. 3b) appears much more complicated, but is,

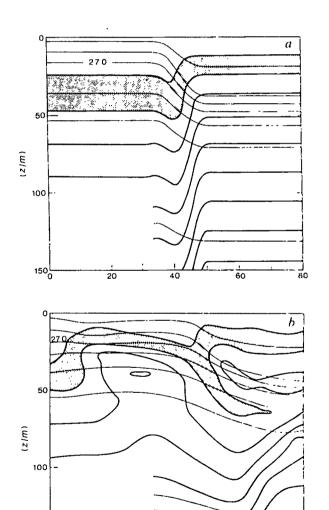

Fig. 2 Depth of isotherms (thick contours) and isopycnals (thin contours) in a vertical section of the upper 150 m in the model domain at positions indicated by the broken lines in Fig. 3 The temperature range between the 18 °C and 19 °C isotherms is shaded.

of course, consistent with the evolving streamlines. A vertical section through the meander (Fig. 2b) shows an intrusion of relatively warm, salty water into the cooler, fresher side of the front. Its axis is inclined to isopycnals. The 18-19 °C temperature range has a 20-km fold.

To understand the isopycnic mechanism of thermohaline intrusions at fronts, it is necessary to discriminate between kinematic and dynamic processes. The latter change the pressure gradient and accelerate the flow; the former do not. Kinematic frontogenesis is the result of a horizontal confluence acting on a passive scalar gradient, which becomes sharpened without changing the flow. The passive gradient of interest here is thermoclinicity, defined as the gradient of temperature on a surface of constant density. Dynamical frontogenesis is the result of a horizontal confluence acting on a dynamically active scalar gradient, which changes the flow as it becomes sharper. The active scalar gradient of interest here is baroclinicity, defined as the gradient of pressure along a surface of constant density. Both processes occur together where there is horizontal confluence of a body of water that is both thermoclinic and baroclinic; that is, one in which the isothermal surfaces are inclined to non-horizontal isopycnic surfaces—the necessary condition for the isopycnic mechanism of thermohaline intrusions. It depends on the kinematic folding of an isothermal surface by the total velocity field, comprising the externally imposed confluence plus the internal circulation arising from the dynamic response to that confluence.

Regional variation of air-sea interaction creates large-scale variations of temperature and salinity in the surface mixed layer. After subduction ¹⁴ into the interior these large-scale variations include both baroclinicity and thermoclinicity. Frontogenesis occurs where there is a confluence in the (mostly laminar-flow ¹⁵ and therefore isopycnic) circulation. The thermoclinicity is sharpened kinematically into a T-S front. The corresponding sharpening of the baroclinicity produces a jet, which is roughly in geostrophic balance with the density gradient. To simulate the cross-front shear that produces intrusions, we have to compute the ageostrophic component of flow associated with the acceleration of the jet. That is done by using the law of isopycnic potential vorticity (IPV) conservation, which states that IPV = $((\zeta + f)/h)$ (d/D) = constant, for a water column bounded by

a pair of isopycnals, where f is the planetary vorticity, and h is the spacing between a pair of isopycnals with mean density D and density difference d. According to this law, h varies with the absolute vorticity, $(\zeta + f)$. Relative vorticity of large-scale motion is negligible compared with f, so the initial IPV before frontogenesis is given by IPV = (f/h(0))/(d/D). As frontogenesis proceeds, changes in h are computed from the local Rossby number (Ro), $h(t)/h(0) = \zeta(t)/f = \text{Ro}(t)$. In practice, the jet scale is usually so small that changes in f can be neglected in comparison with changes in ζ . But as the jet accelerates, the cross-jet shear begins to develop significant relative vorticity (ζ) . The spacing between isopycnals adjusts accordingly, becoming greater on the cyclonic side, and smaller on the anticyclonic side. Continuity of mass is achieved by a cross-jet, ageostrophic flow¹⁶. The structure of this cross-jet circulation depends on the initial profile of the isopycnic gradient of IPV (IPVG)¹⁷. The spring subduction process tends to create a maximum of IPVG near the top of the seasonal thermocline¹⁸. In that case the cross-front ageostrophic circulation comprises a simple cell, with upwelling on the anticyclonic side and downwelling on the cyclonic side of the jet. The circulation tends to flatten isopycnals, limiting the final kinetic energy of the jet, preventing further narrowing and progressively decreasing its depth. The kinematic sharpening of frontal thermoclinicity, effected mainly by the external confluence, is modulated by divergence of the cross-jet ageostrophic circulation. It does not become as sharp as it would have done due to the confluence alone, but, nevertheless, ends up much narrower than the jet. The surface of thermoclinicity maximum, which may have been initially vertical, becomes tipped over, so that it slopes down from the cylonic side to the anticylonic, creating the well-documented slope of the temperature field at a front¹⁹. These characteristics (narrowness and slope of the thermoclinicity maximum relative to the baroclinicity maximum) are important for the structure of thermohaline intrusions which develop as the jet begins to meander unstably.

Frontogenesis, as described above, leads to a two-dimensional structure which can be used as initial conditions for modelling jet instability. The jet is normally unstable, with fastest-growing wavelength and growth rate dependent on the initial IPVG profile. As the meanders grow to large amplitude, they develop curvature vorticity which modulates the spacing between isopycnals, according to the law of IPV conservation described above. Ageostrophic flow from thinning regions to thickening regions advects isotherms isopycnically across the meandering jet core, with a complex vertical structure governed by the initial conditions (and ultimately by the profile of large-scale IPVG before frontogenesis). At any moment, the pattern formed by isotherms on each isopycnic surface depends on the initial thermoclinicity (before frontogenesis) and the time integral of the total flow, including both the geostrophic jet component and the ageostrophic vortex-stretching component.

Our model proves that the isopycnic motion in unstable fronts can produce thermohaline intrusions that slope across isopycnals, a property previously believed to be symptomatic of the double diffusion mechanism. It also emphasizes the three-dimensional character of the velocity field responsible for isopycnic intrusions: one must resist the temptation to seek two-dimensional explanations for intrusions observed in hydrographic sections. Finally, we emphasize that the structure shown in Figs 2 and 3 depended critically on our choice of initial conditions. Cross-isopycnal folding of isotherms is common, but the details vary. The strength of our model technique is that it permits us accurately to simulate the complicated development from explicit large-scale initial conditions to a meandering jet/front with high Rossby number.

Effects of surface heat flux during the 1972 and 1982 El Niño episodes

R. K. Reed

Pacific Marine Environmental Laboratory, National Oceanic and Atmospheric Administration, Seattle, Washington 98115, USA

It has been suggested 1,2 that anomalous surface heat flux may be partly responsible for the initial warming that occurs in the eastern Pacific during El Niño events. Sea surface temperature, net surface heat flux, and winds in the equatorial Pacific are examined here for the 1972 and 1982 El Niño episodes. It is found that surface heat flux and sea surface temperature anomalies tend to have little or negative correlation; thus, surface flux is not of major importance in the formation of thermal anomalies in the central and eastern Pacific.

In northern summer of 1982 a large El Niño episode began. This event produced dramatic effects in the equatorial Pacific Ocean (disappearance of the equatorial undercurrent³, for example) and induced global changes in atmospheric conditions4. Initially, there was considerable discussion of the differences between this event and a 'canonical' episode. Further examination of some of these differences, however, revealed that they largely resulted from similar processes acting in the presence of different initial conditions⁵. It would be of interest to explore in some detail the morphology of the 1982 episode in comparison with a more typical event such as that of 1972. Special emphasis is placed on examining surface heat flux, in an effort to resolve its role in creating thermal anomalies.

The data used for this study were archived ship-of-opportunity weather reports. They were obtained from NOAA's National Climatic Data Center for the periods 1970-79 and January 1982-October 1983. The 1970-79 period was chosen primarily because this was the first data subset for which careful editing procedures had been used to eliminate duplicate reports and other erroneous data. The climatology during this decade was also found to agree closely with those based on longer periods⁶. Surface heat fluxes (insolation, net long-wave radiation, latent heat, sensible heat, and their sum—the net or total heat flux) were calculated from the individual weather reports using empirical formulas⁶, and the fluxes were averaged over 2° latitude by 10° longitude areas to obtain monthly values. Weather elements were also averaged to obtain monthly means.

Estimates of the standard errors of the mean values for each month were made from the calculated intra-month variances for the 2°×10° areas used below. Because the data are very heterogeneous, the estimates are biased high by natural spatial and temporal variability, but they do provide conservative guides. Keeping these caveats in mind, standard errors of the mean sea surface temperature and net heat flux, for an individual month, were calculated as 0.7 °C and 45 W m⁻²

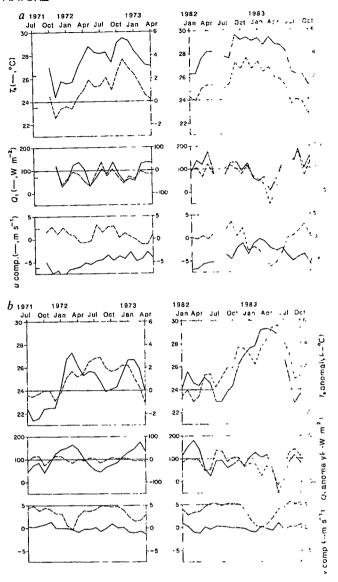

Fig. 1 a, Plots of mean monthly sea surface temperature (T_s , °C), sea surface temperature anomaly (individual monthly mean minus monthly mean for the period 1970-79), mean monthly net or total surface heat flux $(Q_t$, positive for flux into the ocean), net surface heat flux anomaly (individual monthly mean minus monthly mean for the period 1970-79), and the u (east)- and v (north)- components of wind velocity (in m s⁻¹) for the central equatorial Pacific (2° N-2° S, 140-160° W), July 1971-April 1973 and January 1982-October 1983. b, As a except for the eastern equatorial Pacific (2° N-6° S, 80-90° W).

Figure 1a presents information on the evolution of surface properties during both the 1972 and 1982 El Niño episodes for a region in the central Pacific (2° N-2° S, 140-160° W). When more than two of the original four 2°×10° areas had fewer than three observations, the data were omitted. Each monthly mean was typically based on > 10 observations. The east (u) and north (v) components of wind are shown rather than wind speed or anomalies.

During the 1972 episode, surface temperature (T_s) anomalies increased by 2.5 °C between February and May 1972. A further increase occurred during September-November, with a rapid decrease thereafter. (All of the positive temperature anomalies between April 1972 and February 1973 are greater than the standard error estimate above.) Both warming periods coincided with consistently negative surface heat flux (Q_i) anomalies, although some of the values are smaller than the error estimate.

The u-component of wind at this site decreased in magnitude through much of the period, but the winds did not become

The 1982 event evolved differently. There was a small increase in T_s anomaly between February and April 1982 and a large increase between July and September. Relatively constant values then occurred, followed by a fairly rapid decrease after March 1983. Q, anomalies were small before December 1982, but large negative values were present during January-April 1983. This period coincided with small u-component winds but large negative v-component winds, a very anomalous situation⁷.

An interesting difference between the events is that during 1982, formation of the anomalies in the central Pacific led similar changes at the eastern margin by one to two months (Fig. 1b): conversely, in 1972, warming in the central region seemed to generally lag that off South America. Although the magnitudes of the maximum anomalies during the two events in the central region were similar, the duration of anomalies >2 °C was considerably longer in 1982-83 than in 1972.

Figure 1b presents data for a region just off the South American coast (2° N-6° S, 80-90° W). This region has numerous ship-of-opportunity reports, and each 2° × 10° area generally had >20 observations. In 1972, the T_s anomaly appears to have largely formed during January to March, but a subsequent increase occurred from May to August. The second pronounced maximum in T_s , but not in T_s anomaly, in January-February 1973 gives the typical double-peak signature⁸. The Q_t anomalies during this episode were all very small, and the only unusual behaviour in winds is a sharp decrease in the southerlies during February-March 1972.

The first appreciable change in T_e anomaly in 1982 was an increase of 1.9 °C during April-May. (During this period of normal seasonal cooling there was only a small increase in T_{s} .) A second increase in T_s anomaly occurred between August and November 1982. A final warming event took place between February and May 1983, when the T_s anomaly reached +5.4 °C, and cooling started after June. Unlike the 1972 episode, Q anomalies were variable early in the event, but they were all negative from December 1982 to July 1983. The southerly winds were quite weak during January-May 1983, which was of longer duration, and later in the epsiode, than the comparable weakening during 1972.

Figure 1 shows that during both the 'canonical' event of 1972 and the 'summer' event of 1982, heat flux anomalies were small or negative during warming. Thus, surface heat fluxes do not seem to be a significant factor in forming thermal anomalies in the central and eastern ocean. Other studies^{6,9-11} provide support for this conclusion. What processes then produce the marked warming? The surface data set used here does not allow very definitive answers, but other studies (using subsurface thermal data, sea level data, and direct current measurements) have yielded essential agreement on the important mechanisms.

The initiation of warming near the Equator in the central and eastern ocean appears to be consistently induced by heat advection resulting from eastward-moving Kelvin waves^{12,13}. The effects will appear different depending on time of year⁵. If the event is initiated early in the year, as is typical, major warming will first appear off South America because thermal gradients are quite weak along the Equator in the central ocean in southern summer. If the event is triggered in mid-year, as in 1982, warming advances eastward across the ocean in the presence of strong east-west gradients in both the central and eastern ocean. During canonical events, final increases in temperature anomaly in the central ocean may result from a weakening or southward displacement of the South Equatorial Current¹². A southward displacement of this flow¹⁴ also appears to be a factor in the rapid rise in temperature anomaly (Fig. 1b) in early 1983, although the very weak winds then probably also resulted in reduced upwelling.

I thank G. Meyers and E. Sarachik for helpful discussions. The efforts of D. G. Kachel in retrieving the data and programming computations are appreciated. This study was suported by the Equatorial Pacific Ocean Climate Studies (EPOCS) program of NOAA. Contribution 774 from NOAA/Pacific Marine Environmental Laboratory.

Uplift of the shores of the western Mediterranean due to Messinian desiccation and flexural isostasy

Sonya E. Norman & Clement G. Chase

Department of Geosciences, University of Arizona, Tucson, Arizona 85721, USA

During the Messinian Stage (5.5 Myr, Miocene/Pliocene boundary) the 4.2×10^{23} m³ of water that now fills the Mediterranean evaporated. Evidence for this includes palaeogorges 1 km below the present Nile and Rhone valleys and evaporite deposits, sampled by cores and deep-sea drilling^{1,2}, that are thicker than 1 km over much of the Mediterranean³. Two-dimensional flexure models, presented here, indicate that the regionally compensated crustal unwarping from removal of the seawater load would lead to a Messinian geomorphology with an uplifted Mediterranean basin and shoreline bulges along its northwestern and southeastern coasts. These shoreline bulges would cause a reversal of downhill gradient direction in areas with low original seaward slopes. Such a profile would lead to a landward reversal of drainage in rivers with low discharge.

We used a cross-section north from Annaba, Algeria to Marseilles, France to determine present-day ocean depth, which we presume to have been comparable just before the last Messinian desiccation. Vertical deflection from removal of the seawater load along this profile was calculated from an equation derived by Hetenyi4 for distributed block loads and modified by Jordan⁵ for an elastic lithosphere. Figure 1 shows the flexure from 250 km inland in southern France to 300 km south of the coast. We assume a broken plate boundary along the African coast. (Flexure of the European coast is essentially the same for a broken plate as it would be for a plate unbroken at the African margin.) The calculation was first done with a twodimensional seawater load ('Water' in Fig. 1) and was repeated for several flexural rigidity values.

The removal of the load of only the present sea water gives us a flexural response representing the uplift caused by the last desiccation before the final infilling. Another calculation was made for removal of water and the 1.6-km-thick evaporites ('Salt' in Fig. 1). This unloading corresponds to the first Messinian dehydration of the Mediterranean, before its depth had been reduced by deposition of the thick evaporites. Finally, the flexure profiles were superimposed on the present-day topography.

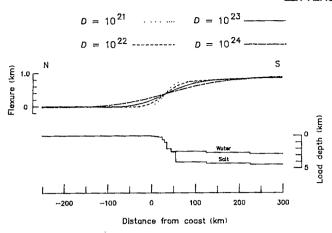

Fig. 1 Uplift of the Mediterranean Basin and 250 km inland on the French coast due to unloading of 2.6 km of water (density 1,000 kg m⁻³) for a range of values of flexural rigidity D (in N m). Load depth profiles are shown at the bottom. The flexure profiles are calculated for removal of present water load only. Topographic relief is not considered.

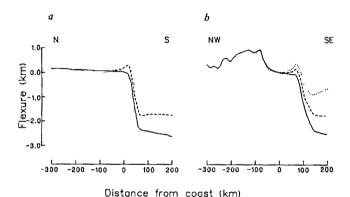

Fig. 2 Flexural effects combined with present topography, giving a regionally compensated palaeotopography profile from 200 km offshore to 300 km onshore, assuming $D = 10^{23}$ N m. Solid line, present profile; broken line, latest Messinian palaeotopography, calculated by removal of water load; dotted line, early Messinian palaeotopography, calculated by removing both water and salt loads (density 2,200 kg m⁻³). a, N7E through Rhone Valley, slight uphill gradient. b, N38W through Cape d'Agde, moderate uphill gradient.

Time-dependent viscous response of the upper mantle should not seriously affect our results. For the size of load and range of flexural rigidities considered here, and for reasonable mantle viscosities, the viscous relaxation time will be <10⁴ yr (ref. 6), while the time span of Messinian dehydration is probably $\sim 10^6$ yr, with episodes of partial refilling^{2,7,8}.

Figure 1 shows the calculated deflection patterns for the seawater load; the effect of superimposing topography on the calculated uplift from seawater and evaporite load is illustrated in Fig. 2. In calculating these palaeotopographic profiles, we work back from the present and show where the present-day topographic surface would have been deformed to by the flexural uplift. We have not estimated the pre-Messinian palaeotopography.

For all flexural rigidity values, the maximum uplift at the centre of the ocean basin is 0.85 km for removal of the seawater load, and 1.9 km for removal of the sea water and evaporites combined. Watts and Ryan9, employing a thermal subsidence model in this area, found the best value for the flexural rigidity D to be 10^{23} N m (this is used for all profiles in Fig. 2). Figure 2a through the Rhone valley (elevation gradient 0.5 m km⁻¹)

has an elevation at the shelf edge greater than that 50-300 km inland. The magnitude of the elevation difference and the location of the axis of lowest topography depends on the flexural rigidity. For $D = 10^{23}$ N m the shelf edge would have been raised 0.18 km above present sea level at the last desiccation (present seawater load removed) and 0.45 km at the first desiccation (seawater and evaporite load removed). The axis of lowest elevation would be 125 km inland from the present coastline for both models. The slight moat immediately off the shelf break is caused by the interaction of the sudden elevation drop with the increase in flexural uplift near the edge of the load. This moat is best developed for the initial uplift (dotted lines in Fig. 2).

Shoreline bulges with inland flexural depressions lead us to consider drainage reversals towards inland basins. There is, however, a problem with applying this to some of the major rivers of the Mediterranean, especially the Rhone. The presence of palaeogorges buried 1 km below present river valleys^{1,2,10} indicates that seaward flow probably persisted throughout the desiccation period. There is still the possibility that further upstream there was a drainage divide, or that during early stages of uplift there was a drainage reversal, but headward cutting (in this case, northward from the Mediterranean) eventually carved through the drainage divide, and cutting of the gorge at the coast was a later event.

The necessary condition for a reversal of drainage is that the change of gradient due to the uplift be faster than the downcutting rate of rivers. Even if large rivers, by virtue of their larger discharge and therefore increased excavating potential, managed to continue flowing in the same direction throughout the Messinian, this model predicts that smaller rivers, with their inherently weaker cutting potential would probably have reversed their drainage direction. Figure 2b demonstrates that a steeper original topographic gradient brings the on-land flexural basin closer to the palaeo-shore and makes it narrower. In addition to the formation of these shore-parallel moats, drainage patterns on the plateaus and in mountains were probably also altered by flexural warping.

This discussion is quantitatively applicable only to the northwestern Mediterranean, and the accuracy there is limited by the assumption of two-dimensionality. The same sort of model should apply to the southeastern Mediterranean, which also has thick evaporites³, although there the broken plate boundaries are more complex and the basin is narrower.

Topographic effects of flexural upwarping due to evaporation of the Mediterranean waters depend on the original topography and flexural rigidity. For southern France, southern Spain, northern Egypt and northern Libya, in areas with topography originally flat enough to have a shoreline bulge, major rivers probably excavated through the bulge as it formed, while lowdischarge rivers probably changed their course toward inland drainage basins. Uplift attending the first desiccation of the Mediterranean, before thick evaporite deposition, should have had about twice the amplitude of the uplift accompanying the last dehydration. Messinian palaeocurrent indicators, location of inland basins and better information on the depth, extent and character of palaeogorges on such rivers as the Rhone, as well as smaller rivers, would test these predictions.

Received 2 October 1985; accepted 1 May 1986.

Thermoluminescence dating of Le Moustier (Dordogne, France)

H. Valladas*, J. M. Geneste†, J. L. Joron‡ & J. P. Chadelle§

* Centre des Faibles Radioactivités, Laboratoire Mixte CNRS-CEA, Avenue de la Terrasse, 91190 Gif-sur-Yvette, France † UA 133 du CNRS; Direction des Antiquités Préhistoriques d'Aquitaine, 26-28 Place Gambetta, 33074 Bordeaux Cedex, France ‡ Groupe des Sciences de la Terre, Laboratoire Pierre Süe, CEN, Saclay, 91191 Gif-sur-Yvette, France § Direction des Antiquités Préhistoriques d'Aquitaine, 26-28 Place Gambetta, 33074 Bordeaux Cedex, France

The chronology of the Neanderthal cultures, commonly called Mousterian, which flourished between ~100,000 and 40,000 yr ago, has not been well established. The lower rock-shelter of Le Moustier provides one of the most important stratigraphic sequences, incorporating ten main Mousterian layers originally identified by Peyrony¹ and two early Upper Palaeolithic layers, the stratigraphy of which is mainly defined in terms of the regional climatic chronostratigraphy derived from the alpine glacial sequence¹⁻⁴. A correlation has recently been proposed between the chronostratigraphy of Dordogne and the past 125,000 yr of the wellestablished stratigraphy based on oceanic oxygen isotope ratios^{5,6}, but the lack of absolute datings of Mousterian settlements makes this correlation uncertain between 100,000 and 40,000 yr BP. We now report dates obtained by thermoluminescence measurements of 34 specimens of burnt flint recovered from the upper 3 m of the Mousterian deposits and from the superimposed Upper Palaeolithic layer. The dates, which range from 56,000 to 40,000 yr BP, allow us to correlate the cold sediment deposits of Le Moustier with cold intervals of the oxygen isotopic record of the Mediterranean Sea during isotopic stage 3.

Of the two major rock-shelters discovered at Le Moustier at the end of the last century, the upper or classic shelter was studied by Lartet and Christy (1863), whereupon Mortillet named the middle Palaeolithic industries Mousterian. The upper shelter was excavated at the beginning of the century^{1,7}. In the other shelter, which is located ~13.5 m below, several Mousterian traditions have been recognized^{1,2}, including typical Mousterian (layers B and J), Denticulate (layers F and I), and Acheulian tradition type A (layer G) and type B (layer H). The stratigraphic sequence, which is ~4 m thick, reveals two types of deposits: (1) the lower group of strata (layers A to F) is made up of waterlain sediments deposited by the floods of the Vézère River; (2) the upper group (layers G to L, Fig. 1a) consists of cryoclastic sediments in which the proportion of anthropological remains can be substantial (especially in layer H).

Each of the 12 main layers has been subdivided on the basis of sedimentation and pollen count data^{4,8}, and the whole sequence has been assigned to the early part of the last glacial period (ancient Würm in the chronostratigraphy of Dordogne^{5,6}). Layer K, overlying the most recent Mousterian layer, contains a mixture of Lower Perigordian (Chatelperronian) and Mousterian tool assemblages. The state of preservation of the Mousterian component in this assemblage suggests possible contamination from below. Layer K has been assigned to the beginning of the recent Würm²⁻⁶, ~35,000 yr ago.

Burnt flints have been widely used for thermoluminescence

Burnt flints have been widely used for thermoluminescence (TL) dating⁹⁻¹⁴; they are common near prehistoric hearths, where some will have been heated to a temperature high enough to erase the thermoluminescence acquired by the minerals during their geological history. Good agreement among the TL dates obtained¹⁵ with four quartz and three flint fragments for the upper Perigordian layer (Gravettian) of La Vigne Brun (Villerest,

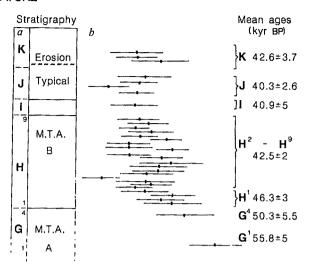

Fig. 1 a, The top Mousterian layers and the Upper Palaeolithic layers of the lower rock-shelter at Le Moustier^{1,4}. The thickness of this sequence is ~3 m. M.T.A., Mousterian of Acheulian tradition, type A (A) and type B (B). b, Horizontal bars representing the TL ages of the burnt flints from Le Moustier as a function of depth. The weighted ages calculated for the respective layers are listed at the right.

Loire, France) suggests that the TL of flint does not fade significantly.

The burnt flints were collected from a small area (30×40 cm) excavated in May 1982 in the north-east corner of the 'witness' sediments (level G to K). Approximately 80 flints of suitable size, showing signs of having been heated, were selected for TL examination. Of these, only 34 were sufficiently well burnt and had satisfactory TL characteristics. Three of these were from the middle part of layer K, 4 from layers J5 to J1, 1 from layer I3, 24 from layers H9 to H1 and 2 from layers G4 and G1. The bottom 1 m of Mousterian deposits (F to A) has not yet yielded burnt flints.

The methods used to treat the samples and to measure their palaeodose and annual dose rate have been described in detail elsewhere 15. The environmental γ dose rate was measured using 28 calcium sulphate dosimeters in copper capsules. These were inserted at the ends of 30-cm-deep horizontal auger holes, which were distributed at ~10-cm intervals from top to bottom, and left buried for 1 yr. As the archaeological layers are also ~10 cm thick, it was impossible to specify the exact location of each sample within a specific layer. The external dose rate received by the flints of a given layer was obtained by taking the average dose measured in the layer itself and in the two adjoining layers, and ranges from 0.33 to 0.54 mGy yr⁻¹ except in layer G. The uranium and thorium contents in the flints were measured by epithermal neutron activation inside a cadmium container^{16,17}, and the potassium content by neutron activation at the Institut Pierre Süe (CEN, Saclay). The internal dose rate usually represents ~50% of the total dose rate, which ranges from 0.67 to 0.90 mGy y⁻¹. The results are reported in Table 1.

The age of each flint and its statistical error are presented as a function of depth in Fig. 1b. The ages (weighted mean) derived for the respective layers range from $\sim 56,000$ to 40,000 yr BP (Table 2). Levels J and H, for which many burnt flints were available, have been dated with better precision (5-6%) than the other levels; for the latter, <3 samples were available and the precision of the results is only $\sim 10\%$.

The time span represented by the layers from which the dated flints were recovered (G to K) is estimated at $15,000 \pm 5,000$ yr. The paucity of data makes it impossible to determine whether there were any occupation gaps during the $\sim 10,000$ yr separating layers G1 from H1. On the other hand, virtually continuous

occupation is suggested by the many layers falling within the shorter time period separating layers H1 and K (6,000 \pm 3,000 yr). Note that, although the ages obtained for the highest Mousterian layer J (40,300 \pm 2,600 yr) and the overlying layer K (42,600 \pm 3,200 yr) are not in accord with the stratigraphy, the magnitude of the experimental errors makes the inversion more

Table 2 Weighted mean ages of levels in which flints were found

Layers	Mean ages (уг вр)
K	$42,600 \pm 3,200$
j	$40,300 \pm 2,600$
I	$40,900 \pm 5,000$
H _o to H ₂	$42,500 \pm 2,000$
H,	$46,300 \pm 3,000$
G_4	$50,300 \pm 5,500$
G_1	$55,800 \pm 5,000$

The errors (statistical plus systematic) at 68% confidence level have been assessed as in ref. 32. A systematic error of $\pm 7.5\%$ has been assumed for the external dose, to take into account possible past variations of the water content of the archaeological sediments (M. J. Aitken, personal communication).

apparent than real. Also, as noted earlier, layer K contained a mixture of Lower Perigordian (Chatelperronian) and Mousterian tools. Thus, it may have been Mousterian flints which were responsible for the date obtained for layer K.

These dates allow us to correlate the stratigraphy of Le Moustier4,5 with the isotopic record and chronology of deep-sea sediments. The ages obtained for levels G to K place their deposition during isotopic stage 3 (ref. 18). A detailed chronology of this stage has recently been proposed by correlating five ash layers contained in cores collected in the central Tyrrhenian Sea with terrestrial volcanic deposits dated by the ¹⁴C and/or the K-Ar method¹⁹. The temperature variations of the Tyrrhenian Sea are much larger than those of the open ocean; consequently, the Tyrrhenian Sea sediments provide an oxygen isotopic signal which is sensitive to both the water temperature and changes in the δ^{18} O content of the water²⁰⁻²². Nevertheless, the Tyrrhenian Sea, like the entire Mediterranean Sea, has yielded isotopic records showing features similar to those in the generally accepted oxygen isotope curve²³; indeed, the classical isotopic stages¹⁸ are easily recognized and within stage 3, a strong climatic variability with a succession of cold and warmer isotopic events has been described19.

. The Tyrrhenian record shows the same climatic trends as those deduced from the analysis of continental pollen in

[†] The β equivalent dose rate per unit of α flux was measured as in ref. 27 and the β equivalent annual dose of flints was calculated using specific fluxes deduced from ref. 28.

[‡] The β dose in flints was calculated using the specific values given in ref. 29. The γ internal dose is <0.01 mGy yr⁻¹.

[§] The external dose rate includes a cosmic contribution of $5-6\times10^{-5}$ Gy yr⁻¹. It has been calculated using the data given in refs 30 and 31; the estimated average thickness of overburden is 9-10 m.

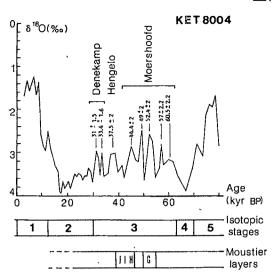

Fig. 2 The dated Mousterian layers are shown below the $\delta^{18}O(\%)$ variations measured in the core KET 8004 collected in the Tyrrhenian Sea. Estimates of the age of the oxygen isotopic events (light δ^{18} O peaks) have been calculated assuming a constant sedimentation rate between two well-dated ash layers¹⁹.

northern Europe, as well as in France and eastern Macedonia²⁴⁻²⁶; the well-dated oxygen isotope peaks (warm events) which occur between 60,000 and 30,000 yr BP (ref. 19) correlate with the continental interstadials dated by the 14C method²⁶. This record provides a fairly good comparison framework for the prehistoric stratigraphy, as it has been obtained in a climatic zone close to southern France.

The dated layers of Le Moustier are shown below the isotopic record of the Tyrrhenian Sea (Fig. 2). The cryoclastic sediments of layers G to K have yielded low pollen counts (<10%), which suggests that these layers were deposited during cold periods^{4,8}. The TL ages obtained for the above-mentioned layers suggest that their deposition occured during the cold periods which developed between 56,000 and 40,000 yr BP on the isotopic record.

We therefore conclude that TL dating of burnt flints should make it possible to obtain close correlation between the floating chronology of the Mousterian epoch based on stratigraphic evidence and the more absolute chronology derived from the isotopic record of sea cores.

The field research at Le Moustier has been supported by the L.S.B. Leakey foundation, Pasadena; California (grant for the Combe-Saunière Dating Project, 1981). We thank G. Valladas for his important contribution to this work and J. L. Reyss for radioactivity analyses. CFR contribution 760.

A putative ancestor for the swordfish-like ichthyosaur Eurhinosaurus

C. McGowan

Department of Vertebrate Palaeontology, Royal Ontario Museum, 100 Queen's Park, Toronto, Ontario, Canada M5S 2C6, and Department of Zoology, University of Toronto

Ichthyosaurs, extinct marine reptiles superficially similar to sharks and dolphins, flourished throughout most of the Mesozoic, but are best represented in the early Jurassic1-5. Hundreds of skeletons are known, principally from the Lower Liassic (Hettangian, Sinemurian and Lower Pleinsbachian) of south-west England and the Upper Liassic (Toarcian) of southern Germany⁶⁻⁹. Among the most specialized is Eurhinosaurus, unique for its long rostrum and shortened mandible, which confers a striking resemblance to the modern swordfish, Xiphias 1,5,10. Known only from the Upper Liassic of Germany, this monotypic genus, like most fossil species, appears suddenly, without antecedents 11-14. The recent discovery of a geologically older (Lower Liassic) ichthyosaur with a partially extended rostrum is therefore of considerable interest. As described here, this specimen, which is too large to be part of a growth series of Eurhinosaurus, appears to be ancestral, and could have given rise to Eurhinosaurus through changes in growth rates of the rostrum and mandible.

The incomplete skeleton of this new ichthyosaur was collected in Somerset in 1984 by D. Costin. It is described below as representing a new genus.

> Class Reptilia Order Ichthyosauria (Family designation awaits revision) Excalibosaurus gen. nov.

Etymology: Excalibur, the mythological sword of Arthurian legend; saurus, Greek (masculine) for lizard.

Diagnosis: Mandible shorter than skull, but exceeding 60% of skull length. Snout extends well beyond anterior tip of mandible, but length of snout (distance between tip of snout and anterior margin of orbit¹⁵) not greatly exceeding length of mandible.

Type species: Excalibosaurus costini gen. et sp. nov. (Fig. 1). Etymology: In honour of D. Costin, through whose diligence and generosity the material was collected and safely deposited in a museum.

Diagnosis: As for genus.

Holotype: Cc 881, a complete skull, with associated forefin, pectoral girdle, vertebrae and ribs, deposited in The City of Bristol Museum and Art Gallery, UK.

Locality and horizon: The foreshore near Lilstock, Somerset, UK (map ref. ST 196 463). Lower Liassic (Sinemurian), horizon provisionally given as the Bucklandi Zone (M. L. K. Curtis, personal communication).

Description: The elongated snout, which projects well beyond the tip of the mandible, distinguishes this from all other ichthyosaurs, except Eurhinosaurus huenei, where the disparity.

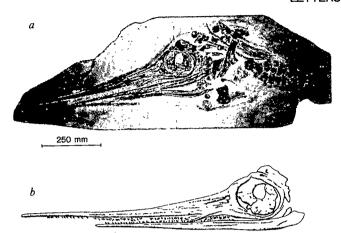

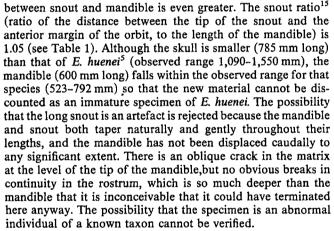

Fig. 1 Excalibosaurus costini gen. et sp. nov. Holotype (Cc881, City of Bristol Museum and Art Gallery). Lower Liassic (Sinemurian) of Lilstock, Somerset, a, Complete specimen; b, diagram of the skull. Scale bar, 250 mm.

Compared with most other Lower Liassic ichthyosaurs, the new species is relatively large, the skull length exceeding that of *Ichthyosaurus communis* and lying at the top end of the range for *I. tenuirostris*³. The new species is, however, smaller than most specimens referred to *Temnodontosaurus*². Its slender teeth extend along most of the free portion of the snout; *Eurhinosaurus huenei* similarly has a dentigerous 'sword'. Further preparation is needed, but the external naris appears bilobed, as in some

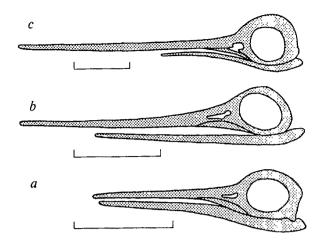

Fig. 2 Ichthyosaur skulls drawn to the same manidbular lengths (a, b), and to the same skull lengths (b, c). a, Ichthyosaurus tenuirostris (based on OUM J10305, Oxford University Museum, and IGS 51236, Institute of Geological Sciences, London) from Lower Liassic (Hettangian-Sinemurian), Street, Somerset. b, Excalibosaurus costini gen. et sp. nov., holotype, from Lower Liassic (Sinemurian), Lilstock, Somerset. The apparent difference in shape between a and b in the vicinity of the jaw joint is an artefact of preservation. c, Eurhinosaurus huenei (based on MNHP 1946-20, Museum National d'Histoire Naturelle, Paris, and FSF 4155, Forschungsinstitut Senckenberg, Frankfurt) from Upper Liassic (Toarcian), Holzmaden. The transition from a to c, via b, could have been effected through an elongation of the rostrum, followed by a reduction in the mandible. Scale bar, 250 mm.

specimens of E. huenet⁵. A similar naris occurs in I. tenuirostris, which has other features in common with the new taxon. This similarity could be used to support a relationship between the three taxa, but it is not a constant feature, and a somewhat similar naris occurs in Leptopterygius burgundiae⁵. The naris of the new species appears to be relatively large. The prenarial¹⁵ ratio (ratio of the distance between the tip of the snout and the anterior margin of the external naris, to the length of the mandible) is relatively higher (0.89) than in I. tenuirostris (0.60). The anterior end of the maxilla has been displaced, but the premaxillary ratio¹⁵ (ratio of the distance between the tip of the snout and the anterior tip of the maxilla, to the length of the mandible) is estimated to be 0.86. The orbital ratio¹⁵ (ratio of the diameter of the orbit to the length of the mandible) is 0.20. The forefin has three digits, with some indication of a fourth; there are

Table 1 Cranial and mandibular ratios for selected ichthyosaurs

		Cranial ratios				Mandibular ratios			
Species	Snout/ skull	Orbit/ skull	Premaxilla/ skull	Prenaris/ skull	Snout/ mandible	Orbit/ mandible	Premaxilla/ mandible	Prenaris/ mandible	
Excalibosaurus costini gen. et sp. nov.	0.80	0.16	0.66	0.68	1.05	0.20	0.86	0.89	
Ichthyosaurus tenuirostris (mean values)	0.75	0.23	0.54	0.62	0.72	0.21	0.52	0.60	
Modified specimen of I. tenuirostris*	0.83	0.16	0.67	0.74	1.09	0.21	0.88	0.97	
Eurhinosaurus huenei (mean values)	0.83	0.12	0.64	0.77	1.64	0.25	1.28	1.53	
Modified specimen of Excalibosaurus costini†	0.80	0.16	0.66	0.68	1.58	0.31	1.29	1.33	

Cranial ratios are measurements (such as the length of the snout) compared with the length of the skull, while in mandibular ratios they are compared with the length of the mandible.

^{*} I. tenuirostris modified by increasing the snout length such that the ratio skull length/mandibular length is the same as in E. costini.

[†] E. costini modified by reducing the length of the mandible such that the ratio mandible length/skull length is the same as in E. huenei.

usually four in I. tenuirostris and up to five in E. huenei. The forefin is about half the length of the mandible, as in I, tenuirostris, whereas in E. huenei it is relatively longer, often exceeding the length of the mandible. There are 12 elements in the longest digit (commencing with the epipodials¹⁶), which is within the observed range for I. tenuirostris, but there are usually more in E. huenei (up to 23). Fin structure, however, is often variable within species, especially in E. huenei⁵.

Aside from its longer snout, the skull of E. costini is similar to that of I. tenuirostris (compare Fig. 2b, a); this results in their having similar orbital ratios, but their other mandibular ratios, and their cranial ratios, are disparate (Table 1). However, if the snout of I. tenuirostris is increased in length until the ratio of skull length/mandibular length corresponds to that of E. costini, their cranial and mandibular ratios converge (Table 1). E. costini could therefore be derived from I. tenuirostris by an elongation of the snout.

E. costini is cranially similar to E. huenei, except in having a relatively longer mandible (Fig. 2b,c); this is reflected in the similarity of their cranial ratios, and the dissimilarity of their mandibular ratios (Table 1). However, if the mandible of E. costini is reduced to 400 mm, giving the same value for the ratio mandible length/skull length as in E. huenei (0.51), its mandibular ratios converge with those of E. huenei (Table 1). E. huenei could therefore be derived from E. costini by mandibular reduction.

If E. huenei evolved from a long-snouted ancestor like I. tenuirostris, through an intermediary like E. costini, what mechanism might have been involved? A change in growth rates of the rostrum and mandible during ontogeny seems plausible, and some insight is gained by studying ontogeny in Xiphias. Larval swordfish have mandibles extending to the tip of the skull¹⁷⁻¹⁹ whereas in adults the mandible is only about one-third of the skull length. These profound changes are effected by relatively small differences in growth rates between the mandible and rostrum (C. McG., in preparation). A small increase in the growth rate of the rostrum in an ichthyosaur like I. tenuirostris could therefore give rise to a descendant like E. costini with an elongated rostrum. This, in turn, could give rise to E. huenei by a reduction in the growth rate of the mandible. Such minor modifications would presumably require relatively small genetic changes, but the morphological, and consequent biological changes would be profound.

I thank M. A. Taylor for bringing the new material to my attention and also thank him, S. Swansborough and M. L. K. Curtis for their help in Bristol. I thank J. Mulock for his drawings; P. Purves for typing; R. Johnson and J. Thomason for reading the manuscript; C. E. McGowan for nomenclatural inspiration; and J. Campsie for classical advice. The genetic control and consequences of kin recognition by the larvae of a colonial marine invertebrate

Richard K. Grosberg* & James F. Quinn†

* Department of Zoology and † Division of Environmental Studies, University of California, Davis, California 95616, USA

The evolution of altruism, cooperation and sociality should be favoured by mechanisms promoting interactions among relatives^{1,2}. In turn, the opportunity for such interactions should be enhanced where related individuals are spatially associated. The simplest explanation for association of kin invokes philopatric, or limited, dispersal3. Alternatively, kin recognition—which is known from a broad array of taxa^{4,5}—can produce similar associations. Neither the prevalence of kin recognition, nor aggregations of kin, are by themselves sufficient to demonstrate that kin recognition plays an important role in the production of nonrandom associations of relatives. To have such a role, kin recognition must promote or inhibit associations of kin beyond the effects of other processes, notably dispersal, that modify spatial patterns. Here we report the results of field experiments showing that sibling planktonic larvae of the sessile colonial ascidian Botryllus schlosseri settle in aggregations that are much stronger than expected from dispersal distance effects alone. Laboratory experiments indicate that larvae distinguish kin on the basis of shared alleles at a highly polymorphic histocompatibility locus known to regulate fusion between adult colonies. This kin recognition mechanism, along with limited dispersal of larvae, promotes co-settlement of histocompatible individuals. Consequently, the probability of fusion between adult colonies is far greater than that expected if larvae settled randomly.

Botryllus schlosseri colonies are founded after a sexually produced planktonic tadpole larva attaches to a firm substratum and metamorphoses. Repeated cycles of asexual multiplication produce a colony of morphologically and genetically identical zooids, connected by a blood vascular system. As in many colonial marine invertebrates, the larvae of several oviparous ascidians can metamorphose soon after release into the plankton⁶⁻¹⁰. In the case of B. schlosseri, our laboratory and field observations, as well as those of others¹¹, demonstrate that larvae can metamorphose—and many do—soon after escaping from their natal colony.

To determine the contribution of larval settlement behaviour to the spatial arrangement of sibling adult colonies, we examined the recruitment pattern of sibling colonies (<4 weeks old) that were founded by larvae, all derived from the same cross, and carrying a rare genetic marker. We identified the marker from an electrophoretic survey of 512 colonies living on the side of the Marine Biological Laboratory Supply Dock in the Eel Pond at Woods Hole, Massachusetts, USA. At the phosphoglucose isomerase locus (PGI), five electromorphs occurred, one of which (PGI-fast) was present in only two of the colonies surveyed. We cross-fertilized these two colonies, then assayed the F_1 colonies for *PGI-fast* homozygotes. One F_1 homozygote was selected as the source colony for marked larvae, and was positioned at the centre of a 1-m diameter circular asbestos-cement panel horizontally suspended 0.5 m below the dock. All zooids in a sexually mature B. schlosseri colony ovulate synchronously approximately weekly. Just before each ovulation, we returned the source colony to the laboratory, where we mated it with a sibling colony homozygous for the same marker allele, then repositioned the source colony on the panel. We left the panel in position for 4 weeks, then mapped and removed all B. schlosseri colonies that had recruited. Colonies were frozen at -80 °C, then analysed electrophoretically. We mapped the panel before any recruited colonies had reached sexual maturity; thus,

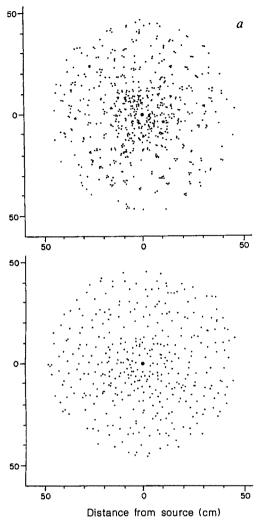

Fig. 1 Maps of the dispersion of Botryllus schlosseri (which settled on the undersurface of a 1-m circular asbestos-cement panel suspended below the Marine Biological Laboratory Supply Dock at Woods Hole, Massachusetts). Small dots depict the locations of colonies. The large dot marks the location of the source colony. a, Map of F₁ colonies (identified by the presence of the PGI-fast allele, see text) derived from source colony. b, Map of colonies not carrying the PGI-fast allele, thus, not derived from the source colony.

colonies homozygous for the *PGI* marker allele were assumed to be siblings originating from the source colony at the centre of the panel. Recruits not carrying the marker allele must have immigrated.

Figure 1a and b show respectively maps of marked and unmarked colonies. To test for spatial association among siblings, we computed the Clark and Evans¹² index of aggregation (R) based on nearest-neighbour distances between sibling colonies. R is the mean nearest-neighbour distance observed, divided by that expected if dispersion were random. Thus, randomly arranged individuals are expected to yield a value for R of 1.0. Values of R significantly <1 indicate aggregation, whereas values >1 indicate overdispersion. The sibling colonies were aggregated as tested by Clark and Evans' significance criteria (R = 0.769: P < 0.001). The unmarked immigrant colonies were significantly overdispersed (R = 1.227; P < 0.001). This overdispersion could result from larval behaviour, or could simply be an artefact of spacing due to colony growth¹³. In any case, the degree of aggregation of siblings differs even more from that of immigrants than it does from random (t-test; P < 0.001).

Figure 1a shows that sibling colonies are clustered around the source colony, perhaps because B. schlosseri larvae can settle

upon release into the plankton. To separate any aggregation caused by sibling recognition from that due to limited dispersal, we constructed a null model based on a bootstrap analysis 14 of the nearest-neighbour data. The locations of colonies were expressed in polar coordinates with the origin at the centre of the source colony: pseudosamples with the same distributions of distances and directions were chosen independently and randomly, with replacement, from the actual coordinates of sibling colonies. The randomized distance and direction coordinates are thus independent in the pseudosamples. This randomization procedure should preserve in the pseudosamples the overall aggregating effect of dispersal distance alone. However, smaller-scale aggregations due to interactions between immediate neighbours will be broken up by the randomization of the angular coordinates. For 500 randomizations, we calculated the value of R produced by the random model. In all cases, the values of R under the random model were substantially greater (mean = 0.897; s.d. = 0.023; range 0.824-0.964) than the observed R = 0.769. This analysis demonstrates that limited dispersal explains only about half the deviation of mean nearestneighbour distance from that expected if settlement were random.

The histocompatibility system known to control fusion and rejection between adult Botryllus colonies may provide a mechanism by which larvae recognize their siblings. Histocompatibility is controlled by a single mendelian locus such that two colonies sharing one or both alleles can fuse by their blood vascular systems. When colonies do not share an allele, rejection, accompanied by necrosis at the site of allogeneic contact, occurs 15-17. Fusion frequencies among pairs of Botryllus colonies collected in the field have been reported to range from 4 to 8% (refs 18, 19). In our studies on the Marine Biological Laboratory Supply Dock, of 500 pairs of colonies collected haphazardly along a 20-m transect, 22 pairs (4.2%) fused. According to the method of Curtis et al.²⁰, at equilibrium, approximately 100 equally frequent histocompatibility alleles would produce the fusion frequency observed in the Eel Pond population. Given such a high level of polymorphism at the histocompatibility locus, the likelihood that any two colonies will share a histocompatibility allele should depend primarily on their pedigree

Because the settled colonies in the field experiments were all full siblings, shared alleles at loci other than the histocompatibility locus could have been used for sibling recognition. Accordingly, we designed laboratory experiments to test whether larval settlement location is better predicted by the histocompatibility type or the relatedness of resident individuals. With a breeding programme using colonies of known histocompatibility genotypes (determined by fusion assays), in a factorial design, we varied independently the effects of pedigree relatedness and histocompatibility genotype of larvae and residents on distance between settled larvae and previously attached residents. Thus, there were four experimental treatments: (1) the residents and larvae were inbred, and shared one histocompatibility allele; (2) the residents and larvae were inbred, but did not share a histocompatibility allele; (3) the residents were fourth-generation outbred descendants of the parents of the larvae, with one shared histocompatibility allele; and (4) the same as (3), but residents and larvae did not share a histocompatibility allele. In outline, the breeding programme was as follows: for treatments (1) and (2), homozygous resident colonies of known histocompatibility genotype (AA) were derived from crosses between heterozygous sibling colonies (AB). Unfusible homozygous colonies (BB) were isolated from the same cross. In treatment (1), introduced larvae (AB) were derived from a cross between the AA and BB full-sibs. In treatment (2), introduced larvae (BB) were derived from a $BB \times BB$ cross from the same sibship used to generate the larvae in treatment (1). Therefore, the introduced larvae in treatments (1) and (2) bear the same pedigree relatedness to the residents, but differ in the presence

Table 1 Two-way analysis of variance on the distance between settled larvae and the nearest resident colony as a function of resident/larval relatedness and histocompatibility types

Source	Sum of squares	Degrees of freedom	F value (P)
Relatedness	57.2	1	1.35 (>0.25)
Histocompatibility type	3,708.5	1 .	87.46 (<0.001)
Replicate	39.8	2	0.47 (>0.63)
Relatedness/			
histocompatibility	174.1	1	4.10 (0.04)
Error	9,964.6	235	

Table 2 Summary of the mean distances between settled larvae and the nearest resident colony according to experimental treatment

Treatment	Mean (mm)	n
Siblings, no shared alleles	14.70	60
Siblings, one shared allele	7.80	60
Outbred, one shared allele	5.15	60
Outbred, no shared alleles	13.92	60

n, Number of observations for each treatment.

of an A histocompatibility allele. For treatments (3) and (4), either AA or BB larvae were introduced into Petri dishes with outbred residents carrying an A allele. These residents were derived after sequential outcrossing with different colonies taken from the field, none of which carried either an A or B allele. After each generation, a colony carrying the A allele was identified (with a fusion assay) and used for subsequent matings. After four generations of outcrossing, single zooids from a heterozygous colony carrying the A histocompatibility allele, and an unknown second allele (differing from B), were used as residents.

For each treatment, we established three replicates, each with 20 resident colonies. The resident colonies were founded by attaching single zooids from a colony of known genotype to random positions on the submerged undersurfaces of the tops of 150-mm plastic Petri dishes. Twenty-four hours later, the dishes were filled with seawater, sealed and kept in the dark. We then introduced 20 larvae through a port in the side of each dish according to the above treatments. One day later, we measured the distance from each settled larva to the nearest

The results of an analysis of variance show that the relatedness of residents and larvae has no discernible effect on nearestneighbour distances (Table 1). In contrast, where larvae and residents shared a histocompatibility allele, the larvae settled significantly closer to the residents (Table 1). Indeed, the mean nearest-neighbour distance between larvae and residents sharing a histocompatibility allele is roughly half that observed when no allele is shared (Table 2). Table 1 shows a marginally significant interaction between the two main effects that is difficult to interpret. However, the minor contribution that this interaction makes to the overall sum of squares suggests that the interaction is biologically unimportant in these experiments.

Our experiments do not eliminate the possibility that larval kin recognition and histocompatibility are closely linked, rather than identical, genetic traits. However, because larval kin recognition increases the likelihood of adjacent colonies being fusible—an otherwise improbable event given the polymorphism of the histocompatibility locus—there are functional grounds for expecting the two processes to be controlled by a single locus.

The promotion of co-settlement of histocompatible colonies, coupled with the restriction of fusion to closely related

genotypes, indicate that colony fusion may be beneficial, but only among kin. In colonial organisms such as Botryllus, fusion may benefit one, or both, members of a chimaera in several ways. First, colony fusion immediately increases colony size. Survivorship is known to be size-dependent in several colonial ascidians (refs 21, 22 and our unpublished observations), sponges^{23,24}, cnidarians²⁵⁻²⁸ and ectoprocts^{29,30}; hence, fusion may reduce the likelihood of total mortality^{29,30}. Second, if the onset of reproduction is size-dependent—as it appears to be in several cnidarians^{28,31} and ascidians^{6,21}—then fusion may lower the age at first reproduction of both members of the chimaera³² In colonial organisms where growth rate is size-dependent^{33,34}. fusion may also increase the probability of subsequent survival and reproduction. Indeed, fusion among juvenile colonial organisms is well known^{32,35}. Third, a chimaera may have different physiological attributes from either component colony, potentially increasing the range of environmental tolerance³² Finally, fused botryllid ascidians (like many other clonal taxa^{36,37}) freely exchange cells that can differentiate into gametes³⁸, and the rate of differentiation may vary genetically³⁸. Under these conditions, somatic cell parasitism, in which one member of a chimaera increases its reproductive output at the expense of the other, can occur³². However, because the polymorphism and genetics of the Botryllus histocompatibility system limit fusion almost entirely to closely related individuals, the parasitic losses, in evolutionary terms, would be considerably less than if the fused colonies were unrelated^{1,39}.

Another potential consequence of close association of kin is increased inbreeding. Laboratory studies suggest that selffertilization is deleterious in B. schlosseri⁴⁰ and, in some congeners, syngamy may not occur if sperm and egg carry the same histocompatibility allele^{41,42}. However, there is no evidence of inbreeding depression in the Eel Pond population of Botryllus schlosseri⁴³. Indeed, studies of other marine invertebrates in which closely related individuals are likely to cross-fertilize provide meagre evidence for inbreeding depression^{9,44}.

Botryllus schlosseri appears to be one of the first species where a functional—and perhaps evolutionary—link between kin recognition, historecognition and the enhancement of colony fusion has been experimentally demonstrated. The prevalence of limited dispersal⁹ and historecognition systems among sessile clonal marine invertebrates³² suggests that such a link may be found in other clonal organisms. Recent studies of congeneic mice show that haplotypic differences in the H-2 region affect mating behaviour⁴⁵; thus, histocompatibility markers could mediate kin recognition in other taxa. Whether the study of marine invertebrates will provide useful insights into the more complex dynamics of kin recognition in mobile, social vertebrates is unclear, but the analogies remain intriguing.

This research was funded by NSF grant OCE 84-07158 to R.K.G. The Committee on Research of the University of California at Davis provided additional support. We thank P. Sherman and M. Marthas for their useful comments.

Leprosy is a spectral disease in which immune responses to Mycobacterium leprae correlate with the clinical, bacteriological and histopathological manifestations of disease^{1,2}, so study of its pathology provides insights into immunoregulatory mechanisms in man. At the tuberculoid pole, patients have few lesions in the skin which contain rare organisms and are able to mount strong cell-mediated immune responses to M. leprae antigens. In contrast, at the lepromatous pole, patients have disseminated skin lesions containing large numbers of acid-fast bacilli and are selectively unresponsive to antigens of M. leprae. M. leprae-induced suppressor cells derived from peripheral blood have been reported to be active in vitro³⁻⁶, yet their in vivo significance has remained unclear. Because the focal point of the immune response to M. leprae is the skin lesion consisting of lymphocytes and macrophages, we have recently developed methods for isolating lymphocytes from skin biopsies of leprosy patients. We report here that two T8 clones derived from lepromatous leprosy skin biopsies, in the presence of lepromin, suppress concanavalin A (Con-A) responses both of peripheral blood mononuclear cells and of T4 clones in an HLA-D (HLA, histocompatibility locus antigen)restricted manner. Moreover, these T8 clones suppressed responses of HLA-D-matched, but not HLA-D-mismatched antigen-responsive T4 clones to M. leprae antigens, indicating that T-cell suppression is major histocompatibility complex (MHC)-restricted at some level in man.

Initial immunohistological studies of skin lesions from patients across the spectrum revealed that cells bearing the T8

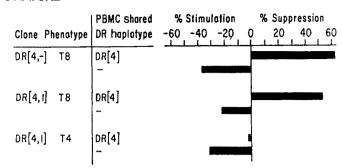

Fig. 1 HLA-D-restricted lepromin-induced suppression of Con A responses of normal peripheral blood mononuclear cells (PBMC) by T8 clones from lepromatous leprosy skin lesions.

Methods. Ellipsoid skin biopsy specimens obtained under local anaesthesia (1% lidocaine with adrenaline) from lepromatous leprosy patients, classified according to the criteria of Ridley and Jopling³⁰, were stripped of epidermis and subcutaneous fat and placed in a tissue sieve fitted with a 64-µm-mesh filter (Belleo Glass Inc.) on a Petri dish containing RPMI 1640 medium with 10% fetal calf serum¹². The tissue was cut into small pieces with a surgical scalpel and extruded through the mesh with a glass rod. The lymphocytes were isolated by Ficoll-Paque (Pharmacia) centrifugation, labelled with fluorescein isothiocyanate-conjugated monoclonal antibodies T4 and T8 (Coulter Immunology), and sorted using a FACS IV (Becton-Dickinson). Long-term culture lines were successfully established from T lymphocytes derived from skin lesions of lepromatous patients. T4 and T8 lymphocytes sorted by FACS to greater than 90% purity were seeded in 96-well flat-bottom Linbro microtitre plates (Flow Laboratories) at 1,000 cells per well. To each well were added 5×10⁵ lethally irradiated (5,000 rad) allogeneic feeder peripheral blood mononuclear cells, RPMI 1640 with penicillin/streptomycin, 10% human AB serum and 10% IL-2 (Electronucleonics). Cultures were incubated at 37 °C in 5% CO2. Every 3 or 4 days thereafter, the cultures were monitored with an inverted phase microscope, transferred to additional wells when necessary and fed with 50% fresh IL-2-containing medium. To avoid suppression from adherent suppressor cells found in blood of lepromatous patients, the lines were cultured with allogeneic or no feeder cells. Some lines were maintained for longer than 11 months using these techniques. Lines from two lepromatous patients It indicts the string tiese techniques. Lines from two epitomators patterns (J.G. and B.P.) were selected for subcloning. Clones were obtained by limiting dilution by seeding 0.3 cells per 20 μ l Terasaki well with 10% AB serum, 5-10% IL-2 and 10⁴ γ -irradiated allogeneic feeder PBMC for 1 week¹³. Positive wells were transferred to a 96-well plate and expanded as above, using 5×10^4 feeder cells, and then to 24-well plates using 5×10^5 feeder cells. When ready for study, T-lymphocyte clones were separated from non-viable cells over Ficoll-Paque and the phenotype was determined by FACS. Antibodies used included T4, T8, anti-HLA-DR (Becton-Dickinson) and anti-IL-2 receptor (Tac, kindly provided by Dr T. Waldmann, or from Becton-Dickinson). Measurement of antigen-induced suppressor activity of lesion derived T-lymphocyte clones was performed using the method of Mehra et al.³. 5×10^4 Cells of a particular T8 clone were admixed with 2×10^5 normal PBMC per microtitre well with and without Dharmendra lepromin (1:10). Con A (2.5 µg ml⁻¹) was added and ³H-thymidine incorporation of triplicate cultures measured at 3 days. Per cent suppression is calculated as 100— (c.p.m. Con A+lepromin/c.p.m. Con A)×100. For each clone, three HLA-DR-matched (A.K., M.R., H.K.) and three HLA-DRmismatched (B.L., G.P., M.S.) donors were used and the results were averaged. A non-reactive T4 clone derived from a lepromatous lesion was substituted for the T8 clones to control for the addition of cells. The c.p.m. above background obtained in the Con A controls averaged 27,471. The results obtained with the T8 clones admixed with the HLA-DR-matched cells differed significantly (P<0.001) when compared with either the T8 clones admixed with HLA-DR-mismatched cells or the T4 'filler' clone assayed with HLA-DR-matched cells, using the z-test approximation to the test for relative difference in Poisson data on actual c.p.m.

(Leu 2a) phenotype were present in excess in lepromatous granulomata as compared with tuberculoid⁷⁻¹⁰. Because the surface markers do not necessarily reflect lymphocyte function within lesions¹¹, simple procedures were developed to extract 10⁵-10⁶ lymphocytes from biopsies of leprosy skin lesions¹². The phenotypic distribution of these cells as determined by fluorescence-activated cell sorter (FACS) analysis was similar to that obtained using immunoperoxidase staining of the tissue sections (T4:T8=0.5:1) in lepromatous and T4:T8=2.0:1 from tuberculoid lesions). In lepromatous patients, the T4/T8 ratio of extracted cells was significantly different from that in blood, indicating that contamination from peripheral blood was negligible. Because we assumed that the lymphocytes in the lesions may be involved in specific immune reactivity and were likely

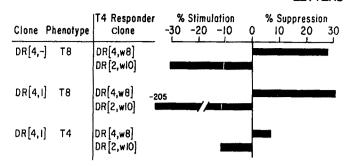

Fig. 2 HLA-D-restricted lepromin-induced suppression of Con A responses of T4 clones by T8 clones from lepromatous leprosy skin lesions.

Methods. Two antigen-reactive T4 clones were derived from skin and blood respectively of two tuberculoid leprosy patients, O.C. and I.B. A T4 line was obtained from peripheral blood by stimulating 1×10⁶ PBMC mI⁻¹ with Dharmendra lepromin (1:10) and 10% AB serum. On day 5, 10% IL-2 was added. On day 6 lymphoblasts were isolated on a Ficoll gradient, then recultured with lepromin, IL-2 and feeder cells. A T4 line was obtained from a tuberculoid skin lesion by extracting T4 cells as described in Fig. 1 legend, and culturing in the presence of lepromin and IL-2. The T4 line from skin was cloned by picking colonies at 4 days from a 35-mm Petri dish containing 1% methylcellulose in RPMI with lepromin (1:10), 10% AB serum, 10% IL-2, 10²-10⁴ lymphoblasts and 4×10^6 irradiated autologous feeder cells per ml. These two T4 lines had previously been found to respond to lepromin but not tetanus toxoid. The T4 line from blood was cloned by limiting dilution as described except that lepromin was included in the cultures at a 1:10 dilution. For testing, 10⁴ cells of an antigenreactive T4 clone were mixed with 105 irradiated autologous PBMC. Lepromin-induced suppression of the Con A response of these T4 clones was determined at 72 h in the presence or absence of 10⁴ cells of the T8 clones. A non-reactive T4 clone was substituted for the T8 clone to control for the addition of cells. The mean c.p.m. above background in three experiments for T4 clone O.C. was 19,059 c.p.m. and for the I.B. clone was 18,150 following Con A stimulation. The results obtained with the T8 clones when admixed with the HLA-DR-matched antigen-reactive T4 clone were significantly different (P < 0.001 by z-test) compared with either the T8 clones when assayed with the mismatched antigenreactive T4 clone or the control T4 'filler' clone admixed with the HLA-DR-matched antigen-reactive T4 clone.

to be activated in situ, cells from lesions were isolated, sorted for T4 and T8 cells and expanded in culture as long-term (up to 11 months) lines in the presence of irradiated feeder cells and interleukin-2 (IL-2) (ref. 12). The cells were cloned by limiting dilution (0.3 cells per well) as described by Lamb et al.13. T4 clones were grown in the presence of lepromin (a human-derived M. leprae preparation) and IL-2 plus autologous or HLA-D-matched feeder cells. T8 clones from lepromatous lesions were grown in the presence of γ -irradiated feeder cells and IL-2 but not antigen. Lepromin seemed to be inhibitory to the growth of T8 clones. The T-cell lines and clones studied expressed both HLA-DR monomorphic determinants and the Tac receptor for IL-2. The T8 clones grow rather slowly and have been difficult to expand in culture. Nevertheless, two clones were selected for study which were suppressive only on stimulation with antigen as described; they have been in culture for 12 and 6 months, respectively.

Because it has been previously observed that lepromatous patients have circulating antigen-specific suppressor T8 cells that inhibit mitogen-induced T-cell proliferation in vitro^{3,4}, lines containing predominantly T8 cells were initially screened for lepromin-induced suppression of the Con A responses of the peripheral blood mononuclear cells (PBMC) of normal donors¹². Lepromin-specific suppression of PBMC from random normal donors was observed in 13 of 32 T8 lines derived from

skin biopsies of 6 lepromatous leprosy patients and in none of 9 T8 lines derived from 6 tuberculoid lesions. The inconsistent suppression of T8 lines from the lesions prompted us to select for single-cell clones and consider possible HLA restriction of suppression.

The HLA types of the donors whose cells were studied are listed in Table 1. The ability of cloned T8 cells from two HLA-DR4 donors to suppress the Con A responses of a panel of six DR4-matched and -mismatched normal donors' PBMC was examined. As illustrated in Fig. 1, there was marked lepromin-induced suppression by the T8 clones of Con A responses of primary lymphocytes from donors sharing DR4 and not those mismatched for DR. There was no obvious correlation with HLA-A or -B-types in these combinations. A Tac⁺, IL-2-dependent T4 clone derived from lepromatous skin of one of the same DR4 donors was used in every experiment to control both for the effect of addition of cloned cells to the wells and for possible competition for IL-2 in the medium. In no case was suppression observed in this control.

Two lepromin-specific T4 clones were derived from blood and skin respectively of two strongly lepromin skin-test-positive patients of differing DR types with tuberculoid leprosy. The ability of the T8 clones to suppress the responses of these T4 clones to mitogen and specific antigen was tested. When DR4matched and DR-mismatched T4 clones and T8 clones were compared for lepromin-induced suppression of Con A responses at 72 hours, again there was striking suppression only of HLA-Dcompatible cultures (Fig. 2). Finally, since the relevance of the lepromin-induced suppression of mitogenic activity to the failure of lepromatous patients to respond to specific antigens remained to be established, we examined the effect of the T8 clones on proliferation of the T4 clones to specific antigen. Since the T4 clones proliferate in response to lepromin at 72 h and fail to show any alloreactivity to MHC-incompatible cells at that time, we were in a unique position to examine whether the T8 clones were capable of suppressing the proliferative response of T4 clones to specific antigen, and to ascertain whether such suppression was MHC-restricted. The results of three experiments (Fig. 3) revealed an HLA-D-restricted suppression by T8 clones of the responses of T4 clones to M. leprae antigens.

While some previous efforts to detect antigen-specific suppression by lymphocytes from lepromatous leprosy patients have not been successful^{14,15}, Ottenhof et al.¹⁶ have recently obtained data similar to those presented here indicating that T8 clones derived from blood of lepromatous patients are able to suppress specific responses of T4 clones from the same patients to lepromin. Nishimura and Sasazuki, who reported the suppression of streptococcal antigen responses of HLA-D-matched T cells by T8 cells from hyporesponsive donors¹⁷, have recently observed suppression of lepromin responses by T8 cells from lepromatous patients (Kikuchi, I., Uzawi, T. and Sasazuki, T.,

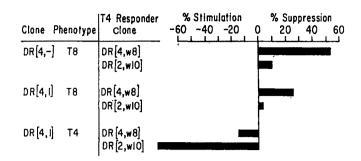

Fig. 3 HLA-D-restricted suppression of the antigen response of T4 clones by T8 clones. Antigen-reactive T4 cloned cells (104) were cultured with 105 irradiated autologous PBMC per 200-µl microwell in RPMI with 10% AB serum, with and without lepromin (1:10), and with and without 104 of each T8 clone. Thymidine incorporation was measured at 72 h. Per cent suppression was determined as 100 - (c.p.m. T4 clone + T8 clone/c.p.m. T4 clone) × 100. A non-reactive T4 clone was substituted for the T8 clone to control for the addition of cells. The mean c.p.m. above background for the lepromin-stimulated T4 clones was 33,662 c.p.m. for I.B. and 24,452 c.p.m. for O.C. respectively. The results obtained with the T8 clones when admixed with the HLA-DR-matched antigenreactive T4 clone were significantly different (P < 0.001 by z-test) compared with either the T8 clones assayed with the mismatched antigen-reactive T4 clone or the control T4 'filler' admixed with the antigen-reactive T4 clone.

in preparation). There are previous reports of T8 suppressor cell clones from human peripheral blood^{18,19}, but we believe that the present observations represent the first evidence that. at some level, human T-cell suppression may be HLA-Drestricted. More detailed analysis will be required to establish that the restriction is in fact localized to the HLA-D region and to learn whether DP, DQ or DR are involved. There is evidence from murine systems that effector suppression is mediated by Ia-positive T cells which are MHC class II-restricted²⁰⁻²²

The nature of the antigen recognized by the suppressor T8 clones remains to be established. We have previously reported that some T-suppressor cells appear to recognize the unique phenolic glycolipid of M. $leprae^{23}$. The recent successful expression of M. leprae antigens in Escherichia coli²⁴ should permit the delineation of protein antigens and epitopes recognized by T-suppressor and T-helper cells.

The existence of monocytes in lepromatous patients with the ability to suppress mitogen and antigen responses in vitro has been reported by a number of laboratories 3,5,6,25,26. The nonspecific nature of the monocyte suppression and the selective unresponsiveness of lepromatous patients to antigens of M. leprae suggest that more specific mechanisms must be involved as well. A number of lines of evidence suggest that T-suppressor cells may contribute to the failure of the immune system in lepromatous patients to kill and clear M. leprae from their lesions. Clearly, large numbers of M. leprae coexist in lesions with T8 cells which show antigen-induced suppressor activity in vitro. There is a marked diminution of T4 cells containing IL-2 in these same lesions, although many are positive for the IL-2 (Tac) receptor²⁷. We have found that the in vitro suppression of Con A responses by T8 cells from lepromatous patients is specific for the stage of the disease^{3,4}. Finally, T8 suppressor activity present in 10 lepromatous patients disappeared after successful immunotherapy by vaccination with live BCG together with killed M. leprae28

At least four possible mechanisms could be involved in the selective immunological unresponsiveness of lepromatous leprosy patients: (1) M. leprae or a secreted metabolic product could inhibit appropriate antigen presentation to T4 cells by macrophages, Langerhans or dendritic cells, resulting in development of T8 suppressor cells; (2) T8 suppressor cells could secrete a suppressor factor (TsF) that blocks responsiveness of specific T4 cells to M. leprae antigens; (3) T8 suppressor cells could lyse T4 cells in an antigen- and MHC-restricted manner; and (4) T8 cells could interact with and 'veto' antigenreactive T4 cells without killing them²⁹

We believe this to be the first report of isolation of genetically restricted T-suppressor cell clones from lesions of a human disease. Considerably more detailed study will be required to establish the precise nature of the genetic restrictions involved in unresponsiveness in man. Nevertheless, we hope that this approach will be useful in exploring the nature of genetic restrictions and receptor gene organization in suppressor T cells. and the role of these cells in regulating immunological unresponsiveness in man.

Cloned suppressor T cells from a lepromatous leprosy patient suppress *Mycobacterium leprae* reactive helper T cells

Tom H. M. Ottenhoff*, Diënne G. Elferink*, Paul R. Klatser† & René R. P. de Vries*

* Department of Immunohaematology and Bloodbank, University Hospital Leiden, 2333 AA Leiden, The Netherlands † Laboratory of Tropical Hygiene, Royal Tropical Institute, 1105 AZ Amsterdam, The Netherlands

Leprosy is a chronic infectious disease caused by Mycobacterium leprae. A characteristic feature of the disease is its remarkable spectrum of clinical symptoms correlating with the cellular immune responsiveness of the patient1. At one pole of this spectrum are tuberculoid patients displaying both acquired cell-mediated immunity and delayed type hypersensitivity against the bacillus²⁻⁴. At the other pole are lepromatous patients which show a specific T-cell unresponsiveneess against M. leprae⁵. In between those two poles variable degrees of tuberculoid and lepromatous features may be seen in borderline leprosy patients. Thus far, studies on the mechanism of the antigen specific unresponsiveness in lepromatous leprosy have been contradictory and difficult to interpret, probably because of the use of heterogeneous cell populations in those experiments⁶⁻¹⁰. We have now succeeded in cloning M. leprae stimulated T-helper (TH) as well as T-suppressor (TS) cells from a borderline lepromatous patient. The Ts-clones of this patient specifically suppress reponses of peripheral TH cells as well as TH clones induced by both M. leprae and other mycobacteria, but not unrelated antigen or mitogen. These Ts cells also completely suppress T_H cell responses against a M. leprae specific protein with a relative molecular mass of 36,000 (36K), suggesting the presence of a suppression inducing determinant on this 36K M. leprae protein.

In contrast to M. leprae-activated and interleukin-2 (IL-2)propagated T-cell lines and clones derived from tuberculoid leprosy patients, similar T-cell lines of (borderline) lepromatous leprosy patients consistently failed to show a proliferative response against M. leprae antigens presented by autologous or allogeneic histocompatibility locus antigens (HLA) class II matched antigen presenting cells (APC) (data not shown). This lack of proliferation by cultured T cells to M. leprae was also observed when the peripheral blood mononuclear cells (PBMNC) of such (borderline) lepromatous patients did proliferate to M. leprae. We selected one such a borderline lepromatous patient whose peripheral T cells did proliferate against M. leprae as well as to unrelated antigens like herpes simplex virus (HSV) and mitogen (phytohaemagglutinin; PHA) because this might enable us to study both helper and possibly suppressor T-cell responses against M. leprae. We then tested the M. leprae-non-responsive T-cell line on autologous antigen activated peripheral T_H cells, thereby circumventing allogeneic effects. As shown in Fig. 1, the M. leprae-non-responsive T-cell line suppressed specifically and strongly M. leprae but not HSV or PHA responses. Peripheral responding T cells were mainly positive for the CD4 antigen. The same result was obtained with five other M. leprae induced T cell lines of the same patient, all of which were antigen non responsive but IL-2 responsive.

Cloned T cells were derived from one such a line. None of these clones proliferated to *M. leprae* in the presence of APC, similar to the parental T-cell line (data not shown). All these clones suppressed *M. leprae* but not HSV-specific responses of peripheral T cells (Table 1). Peripheral T-cell responses against *M. tuberculosis*, *M. fortuitum* or PPD (purified protein derivative of *M. tuberculosis*) were also suppressed in variable degrees by

these T_S -clones. The cell surface marker phenotypes of the T_S -cell line and T_S clones are also shown in Table 1. All T_S -clones were CD3 positive, confirming the T-cell lineage nature of these cells. All T_S clones were also CD8 positive, whereas some showed a weak (1D8, 1D11) or clear (1E9) double staining for CD4. The simultaneous expression of CD4 and CD8 by peripheral T cells and T-cell clones has been reported recently 11,12 . The clones strongly expressed HLA-DR antigens whereas the expression of DQ and DP varied.

Recently the genes for the five major proteins of M. leprae have been cloned and expressed in Escherichia coli¹³. One of these five proteins is a M. leprae specific 36K protein¹³⁻¹⁵. This protein was recently shown to contain several different antigenic determinants capable of stimulating helper T cells. These determinants include both M. leprae specific and cross-reactive ones as defined by M. leprae specific and cross reactive T-helper clones from tuberculoid patients¹⁶. Peripheral T cells of the suppressor cell donor reacted with this 36K protein. This offered the possibility to determine whether these 36K reactive T_H cells could be suppressed by the autologous Ts cells. A negative result would indicate that the epitope(s) recognized by Ts cells resides neither on the 36K protein nor on the 36K reactive TH cells, thus enabling us to dissociate easily the induction of M. leprae reactive T_H and T_S. This is of course not only important for experimental purposes, but also for the prevention (vaccine) and maybe even therapy of leprosy. However, as shown in Fig. 2, the 36K response could be inhibited completely by the T_S cells. This result may indicate that the 36K protein in addition to helper epitopes also contains at least one suppressor epitope.

Table 1 T_S clones and line suppress the response of PBMNC to M. leprae and other mycobacteria but not unrelated antigen

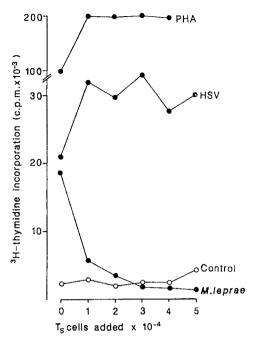

Ts clone	1D8	1D11	1E9	1D10	3D2	1G2	Ts line
[CD phenotype] % Suppression of response of PBMNC to:	[4,8]	[4,8]	[4(8)]	[8]	[8]	[8]	[4,8]
M. leprae	70	95	73	53	54	53	88
M. tuberculosis	24	55	70	44	39	ND	80
M. fortuitum	20	48	72	34	40	ND	91
PPD	2	44	56	50	50	ND	76
HSV	-250	12	8	-231	-56	5	-59

The results are expressed as the percentage suppression of peripheral T cell responses against the respective antigens after the addition of 3×10^4 T suppressor cells, as calculated with the formula (1-c.p.m. of peripheral T cells cultured in the presence of suppressor T cells/c.p.m. of peripheral T cells in the absence of suppressor T cells) $\times 100\%$. Peripheral T-cell responses in the absence of suppressor cells against M. leprae were: 21,920 c.p.m., against M. luberculosis: 26,570, against M. fortuitum: 15,605, against PPD:6,060 and against HSV:29,300. Responses in the absence of antigen were 970 c.p.m. All results are given as the mean c.p.m. of duplicate cultures. Standard deviations did not exceed 20%. The CD4,8 phentoypes of the T cell line and clones are shown. ND, not determined.

Methods. The cultures were set up as described in Fig. 1 legend. The antigens tested in addition were ultrasonicates of whole mycobacteria (20 µg ml⁻¹) and PPD (5.0 µg ml⁻¹). From the suppressor T-cell line, clones were prepared by cloning the cells (1D8, 1D10, 1D11:10 cells per well; 1E9, 3D2, 1G2; 0.5 cell per well) on the feeder cell mixture described in the legend of Fig. 1, supplemented with Leuko Agglutinin A (1 μg ml⁻¹) (Pharmacia) and expanding the cultures in the presence of exogeneous IL-2. This cycle was repeated several times. The cell surface marker phenotypes of the different T cells were determined by a standard indirect immunofluorescence technique as described in ref. 32. The monoclonal antibodies used were OKT3 (Ortho) for the CD3 marker, RIV-6 (anti-T4/leu 3; National Institute of Public Health, Bilthoven, Netherlands) for the CD4 marker, FK18 (anti-T8/leu2; gift of F. Koning) for the CD8 marker, B8.11.2 (anti HLA-DR; gift of B. Malissen), SPV-L3 (anti HLA-DQ; gift of H. Spits) and B7/21 (anti HLA-DP; gift of F. Bach) for respectively HLA-DR, DQ and DP antigens.

Fig. 1 Antigen specific suppression of *M. leprae* but not herpes simplex virus (HSV) or PHA induced proliferative peripheral T cell responses by a *M. leprae* induced and in IL-2 grown suppressor T cell line. The latter was added to 10⁵ PBMNC in concentrations of 0, 1, 2, 3, 4 or 5×10^4 cells per culture. The results are expressed as the mean c.p.m. of duplicate cultures (³H-thymidine incorporation). Standard deviations mostly did not exceed 20%. *M. leprae* antigens isolated from human lepromas and from armadillo infected tissue induced similar suppression.

Methods. PBMNC of a borderline lepromatous leprosy patient were isolated from heparinized venous blood by Ficoll-Isopaque density centrifugation (Pharmacy, University Hospital Leiden), washed three times in Hanks' balanced salt solution (Gibco) and resuspended in Iscove's modified Dulbecco's medium (IMDM; Gibco) supplemented with 100 µg ml⁻¹ streptomycin, 100 U ml⁻¹ penicillin (both Flow Laboratories) and 10% heat inactivated human AB serum. The diagnosis of this and other patients used for this study was based on regular clinical examination, lepromin skin test and skin biopsy histology by Dr D. L. Leiker, Department of Dermatology, University Hospital of Amsterdam, the Netherlands. A standard lymphocyte transformation test was set up with 105 PBMNC per culture, to which antigen was added. Antigens tested were Dharmendra lepromin, consisting of bacilli isolated from human lepromas (obtained from the Centre for Infectious Diseases, Center for Disease Control, Atlanta, USA; 1:80 dilution) and herpes simplex virus (obtained from the National Institute of Public Health, Bilthoven, The Netherlands; 1:64 dilution). From the start of the culture, either no or 1, 2, 3, 4 or 5×10^4 T cells of the nonresponsive T-cell line (see above) were added to the culture. The cultures were set up in flat-bottomed 96-well microtitre plates (Greiner), incubated at 37 °C in a fully humidified 5% CO2-air mixture for 5 days after which 1.0 µCi ³H-thymidine was added to each well; the cultures were collected 16 h later on glass-fibre filters using a semiautomatic sample harvester. 3H-TdR

incorporation was assessed by liquid scintillation counting. The T cell line was generated as described previously ^{16,30}. In brief, PBMNC were restimulated in vitro with an optimal concentration of Dharmendra lepromin (1:80) in 24-well tissue culture plates. T-cell blasts were then cultured for 10 days in the presence of 20% IL-2 containing medium (Lymfocult-T, Biotest). The cells were tested then for antigen-induced proliferation in the presence of autologous APC and antigen but failed to show a response. The cells were then restimulated with a feeder mixture consisting of irradiated autologous EBV-BC as autologous APC³¹ (10⁵ cells ml⁻¹), PBMNC from three or four random donors (10⁶ cells ml⁻¹) and Dharmendra lepromin (1:80). The cultures were further expanded in the presence of IL-2. The cells were then collected, tested again for non responsiveness against antigen and used for experiments. All cells were cultured in IMDM supplemented with 10% human AB serum.

This 36K epitope then would be the first M. leprae suppressor epitope on a M. leprae protein, because we consider it unlikely that the 36K protein would contain the M. leprae specific phenolic glycolipid, which has been reported to induce suppression of concanavalin-A stimulated PBMNC of lepromatous patients^{5,7}. The co-existence of both helper and suppressor epitopes on the 36K protein would closely resemble the situation for other immunogenic proteins like hen egg white lysozyme¹⁷, β-galactosidase¹⁸ and a 185K streptococcal protein¹⁹. For the first two protein antigens it has been shown that the putative suppressor epitope has to be situated on the same molecule or fragment as the helper epitope in order to induce suppression of the immune response^{20,21}. This may be true for the 36K protein as well. A second explanation however for the suppression of T_H cell responses against the 36K M. leprae protein would be that that T_S cells specifically recognize (an) idiotypic determinant(s) on the 36K responsive T_H cells. Whatever the mechanism of the observed suppression, it is clear the activation of antigen specific suppressor cells places constraints on the use of such proteins for prophylactic immunization. We hope that a suppressor epitope will turn out to be the right explanation, because then the rational design of a synthetic M. leprae vaccine would imply the selection of helper epitopes and/or the molecular dissociation of helper from suppressor epitopes²². If the mechanism would appear to be an anti-idiotypic one such a vaccine strategy would not easily result in the circumvention of M. leprae reactive suppression in susceptible individuals.

In order to obtain more insight in the specificity and mechanism of the supression mediated by these T_S clones, we isolated CD4-positive clones from the same patient that proliferated to *M. leprae* by cloning the cells relatively early (96 hours) after a single exposure to *M. leprae*. This procedure was followed because helper T-cell growth was reported to precede that of suppressor T cells in time²³. The thus isolated supposedly T_H clones responded to *M. leprae* specific or cross-reactive determinants, like was observed for tuberculoid patients and healthy contacts^{16,24} and were HLA-DR or -DP restricted in their response. As shown in Table 2, T_S clones could suppress both

 $M.\ leprae$ specific and cross-reactive T_H clones in a number of cases (1G2, 1D11). Other T_S clones appeared to suppress only some (1E9) or no (1D10) T_H clones, although suppressing the $M.\ leprae$ response of PBMNC. Apart from providing a (negative) control for the specific suppression on T_H clones, the latter observation may either indicate that in order to complete and/or amplify the suppressor circuit, cells other than the T_S clones have to be recruited. Alternatively, the T_S clones may be anti-idiotypic and would not suppress T_H clones (2F9, 2B2) which carry another idiotypic determinant than that seen by the T_S cell. However, probably the most important aspect of the data presented in Table 2 is the fact that the same T_S clones which suppressed T_H responses to cross-reactive mycobacterial anti-gens (T_S clones 1G2 and 1D11, see also Table 1) are also able

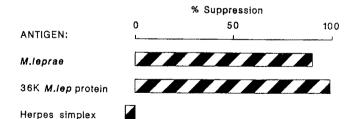

Fig. 2 Antigen-specific suppression of peripheral T-cell responses against a purified M. leprae 36K protein. The results are expressed as the percentage suppression after the addition of 3×10^4 T suppressor cells (see legend table 1). The response in the absence of T suppressor cells against the 36K protein was 12,020 c.p.m., against M. leprae 27,040 c.p.m., and against HSV 14,255. Responses with no antigen in the culture were 1,030 c.p.m. in the absence and 428 c.p.m. in the presence of the T suppressor cells. Standard deviations did not exceed 20%. The suppressor T-cell line was tested in this experiment. Similar results have now been obtained with T_S clones. The tested 36K protein was purified by affinity chromatography using monoclonal antibody F47-9-1 (refs 14, 15) coupled to cyanogen bromide-activated Sepharose 4B, followed by elution with 0.1 M diethylamine pH 11.5. The protein was tested in a concentration of 5.6 μ g ml⁻¹.

Table 2 T_S clones suppress the M. leprae response of some but not all M. lenrae reactive T., clones of the same nations

THE OLD INC.		ne patient	•			
	Proliferative T ₁₁ clone					
	2F9	2B2	2F6			
Proliferation to M. leprae: Proliferation to	+	+	+			
other mycobacteria:	-	±	+			
T _S clone added	Percer	ntage suppi	ression			
1G2	411	47	63			
1D11	55 .	52	62			
1E9	5	-1	30			
1D10	-51	-13	4			

Results are expressed as the percentage suppression (see table 1). M. leprae specific, (2F9), partly crossreactive (2B2) or completely crossreactive (2F6) T_H clones of the same patient were induced to proliferate by autologous irradiated APC and M. leprae antigen as described recently 16,26. Briefly, 10⁴ TLC cells were cocultured with 5×10⁴ APC (40 Gy irradiated) and Dharmendra lepromin (1:80) for 72 h, after which ³H-TdR was added as described in Fig. 1 legend. The mean c.p.m. of the T_H clones in the absence of suppressor T cells were 36,780 for 2F9, 8,252 for 2B2 and 8,694 for 2F6. At the start of the culture either no or 3×10^4 suppressor cells were added. Background proliferation in cultures containing T_H and T_S cells without antigen was always less than 440 c.p.m. The percentage of suppression was calculated as described in the legend of Fig. 1. Standard deviations did not exceed

to suppress a T_H clone directed against an M. leprae specific epitope. This might indicate that cross-reactive T_S clones as described in this paper although not M. leprae specific, could play an essential role in the M. leprae specific unresponsiveness observed in lepromatous leprosy. It is interesting that in several instances a marked depresson of M. tuberculosis and BCG responses has been noted in lepromatous leprosy patients 25,26. In the light of our findings this may be explained at least in part by M. leprae induced crossreactive Ts cells. We deliberately selected a borderline lepromatous leprosy patient, which was not unresponsive to M. leprae in order to be able to generate both T_H and T_S clones. Therefore we have to be cautious in generalizing this observation because it is generally assumed that lepromatous leprosy patients are nonresponsive to M. leprae but remain good responders towards other mycobacteria (reviewed in refs 1, 5). Interestingly, it has recently been suggested that such patients—in contrast to tuberculoid patients and healthy contacts—do not respond to cross reactive or common antigens on other mycobacteria, but rather to the species specific antigens except of course the M. leprae specific ones (refs 25, 27, 28; G. A. W. Rook, submitted for publication). The question then arises why the M. leprae induced crossreactive Ts cells could not also suppress TH responses against the species specific antigens of other mycobacteria than M. leprae. Extending the antigen bridging model (refs 20, 21) we propose that these T_S cells might only suppress T_H cells when both the suppressor epitope (that is, the crossreactive M. leprae suppressor epitope) and the helper epitope to which the M. leprae reactive T_H cells were induced originally (that is, either a M. leprae specific or a crossreactive helper epitope) are expressed by the same molecule. This prerequisite is not met in the case of T_H responses against the species specific helper epitopes of other mycobacteria than M. leprae: since these helper epitopes by definition are not situated on molecules shared with M. leprae, T_H responses against these non-M. leprae epitopes can evade suppression by cross-reactive T_S cells irrespective of the presence of a crossreactive suppressor epitope on that same molecule. Qualitative and quantitative differences in the sensitization towards those species specific helper epitopes in lepromatous leprosy patients might thus account for at least part of the heterogeneity observed in responsiveness against other mycobacteria in lepromatous leprosy.

Since the observed suppression of peripheral T_H-cell responses and T_H clones might be explained by cytotoxicity against either responding antigen specific TH cells or APC, we investigated whether peripheral cells activated by M. leprae or HSV, or autologous Epstein-Barr virus-B cells, pulsed or unpulsed with M. leprae, or M. leprae reactive TH clones could be lysed by suppressor cells. However, no specific lysis of these targets by the suppressor T-cell line and T_s clones was observed, whereas a control cytotoxic T-cell line specific for HLA-A2 strongly lysed all targets tested. Therefore these results excluded cytotoxicity as a possible mechanism of suppression.

Finally, we were interested to know whether these T_S clones were HLA-restricted or not and if so by which HLA molecules and epitopes. Modlin et al.29 have recently claimed that suppressor T cells from the skin lesions of lepromatous leprosy patients may be restricted by HLA-DR. Our own preliminary data obtained with both panel and family studies in which the To cells were mixed with allogeneic TH cells have indeed also shown evidence for some kind of restriction. However, this was not simply associated with HLA-class I, -DR or -DO alleles. Thus far, we have been unable to abolish the suppression with HLA-class I or HLA-DQ specific monoclonal antibodies, but HLA-DR antibodies could do so in certain TH-Ts cell combinations. Thus, although HLA-DR might be involved, the genetic restriction of T_S cells seems to be more complex than that of T_H cells.

The lines and clones described in this paper can be made available to interested colleagues.

We thank Professor J. J. van Rood for his support for this project; Dr. R. C. Good for M. leprae antigen; Professor D. L. Leiker for help and cooperation; the patients for donating blood; Earl Johanns and John Haanen for technical assistance; Fons UytdeHaag for HSV antigens; Madeleine de Wit for isolating the 36K protein; Arend Kolk for monoclonal antibodies; Jos Pool for assistance in the CML test and in preparing serum pools, Annemarie Termijtelen for helpful discussions and Ellen van der Willik for preparing of the manuscript. This study was supported in part by the Foundation for Medical Research (FUNGO grant 900-509-099), the Immunology of Leprosy (IMMLEP) component of the UNDP/WORLD Bank/WHO Special Programme for Research and Training in Tropical Diseases, the Netherlands Leprosy Relief Association (NSL). and the J. A. Cohen Institute for Radiopathology and Radiation Protection (IRS).

Retinal ganglion cells lose response to laminin with maturation

J. Cohen*, J. F. Burne*, J. Winter† & P. Bartlett‡

The decisive role played by adhesive interactions between neuronal processes and the culture substrate in determining the form and extent of neurite outgrowth in vitro1,2 has greatly influenced ideas about the mechanisms of axonal growth and guidance in the vertebrate nervous system. These studies have also helped to identify adhesive molecules that might be involved in guiding axonal growth in vivo. One candidate molecule is laminin, a major glycoprotein of basal laminae3 which has been shown to induce a wide variety of embryonic neurones to extend neurites in culture4-8. Moreover, laminin is found in large amounts in injured nerves that can successfully regenerate but is absent from nerves where regeneration fails⁹⁻¹¹. However, it is unclear to what extent the mechanisms that regulate axonal regeneration also operate in the embryo when axon outgrowth is initiated. Here we have examined the substrate requirements for neurite outgrowth in vitro by chick embryo retinal ganglion cells, the only cells in the retina to send axons to the brain. We show that while retinal ganglion cells from embryonic day 6 (E6) chicks extend profuse neurites on laminin, those from E11 do not, although they retain the ability to extend neurites on astrocytes via a laminin-independent mechanism. This represents the first evidence that central nervous system neurones may undergo a change in their substrate requirements for neurite outgrowth as they mature.

In the chick retina most retinal ganglion cells (RGC) become post-mitotic between E3 and E7 (ref. 12), and during this period axon outgrowth is largely confined within the retina, optic stalk and tract. By E11 the production of RGC has virtually ceased and the majority of optic axons have entered their target tissue, the optic tectum¹³. To compare the behaviour of RGC in cultures of E6 and E11 retinal cells, we have used a monoclonal antibody against chicken Thy-1 glycoprotein¹⁴, an immunologically distinct homologue of mammalian Thy-1 (ref. 15). As previously shown for the immature rat retina^{16,17}, Thy-1 is restricted to RGC in cryostat sections of the embryonic chick retina (Fig. 1). Whereas optic nerve transection experiments in the rat suggest

Fig. 1 Localization of Thy-1 antigen in embryonic chick retina. Phase-contrast (a,c) and fluorescence (b,d) photomicrographs of E11 (a,b) and E20 (c,d) cryostat sections of retina. b, At stage E11, monoclonal anti-Thy-1 antibody binds only to cells in the retinal ganglion cell layer (RGC) and axons in the optic fibre layer (OFL) (d). At E20, immunofluorescence staining is more intense and extends also to the inner plexiform layer (IPL) but is absent from all other retinal layers. Both a and c show dorsal-central regions of retina adjacent to the optic nerve head. Scale bars, 50 μ m.

Methods. Whole eyes were fixed in paraformaldehydelysine-periodate 36 , cryoprotected with sucrose, infiltrated with OCT embedding compound, and frozen in liquid nitrogen. Cryostat sections $(6-10\,\mu\text{m})$ were cut in the horizontal plane, dried on polylysine-coated (PL) slides and incubated overnight at 4 °C with monoclonal anti-chick Thy-1 antibody (ascites fluid diluted 1:100) followed successively by incubation for 2 h at room temperature in biotinylated sheep anti-mouse immunoglobulin and streptavidin-fluorescein (Amersham; diluted 1:100). Sections were mounted in glycerol containing 1,4-diazobicyclo-(2,2,2)octane (DABCO) to inhibit fading of fluorescence 37 , and photographed on a Zeiss Universal microscope.

that some bipolar and amacrine neurones might also express Thy-1 in the mature retina¹⁸, most of these cells differentiate after E11 in the chick and are unlikely to account for a significant proportion of the Thy-1⁺ cells seen in our cultures.

Immunoreactive Thy-1 antigen was first detectable in situ at E5 as faint punctate deposits in the immature RGC layer (not shown). By E11 the antigen was also detectable in the optic fibre layer (OFL) (Fig. 1a, b), and at E20 it was found in regions containing RGC cell bodies, their axons and dendrites, but was absent from other retinal layers (Fig. 1c, d). In retinal suspensions at E6 and E11, 2-5% of these cells were Thy-1⁺ (not shown), including more than 90% of the larger (>10 μ m diameter) cell bodies.

When cells dissociated from E6 or E11 retina were plated on polylysine (PL) coated glass coverslips at a sufficiently low density ($\leq 50,000 \text{ cells cm}^{-2}$) to keep them separate, >80% of the Thy-1⁺ cells attached within 2 h. However, after 16 h < 10% had extended neurites and most had begun to degenerate. Similar results were obtained with a variety of substrates, including polyornithine, fibronectin, rat-tail collagen and fibroblast ghosts (not shown). However, when E6 cells were grown on laminin, most Thy-1+ cells (>75%; Fig. 3) extended long neurites (Fig. 2a, b); profuse, non-fasciculated outgrowth of Thy-1⁺ processes, which also stained with a monoclonal antineurofilament antibody RT97 (not shown), was evident within a few hours of plating, being maximal at 48-72 h, by which time some Thy-1+ RT97+ neurites extended distances in excess of 50 cell diameters (>600 μ m). By contrast, <10% of Thy-1 $^{+}$ cells in cultures of E11 retina extended neurites on laminin and this growth pattern was indistinguishable from that on polylysine (Figs 2c, d, 3). The same stage-dependent response was also seen on a substrate (ACM) consisting of polylysine binding material from culture medium conditioned by rat type-1 astrocytes¹⁹ (Fig. 3). Although we have not characterized the factor in ACM, previous studies with a variety of culture medium-derived neurite-promoting factors make it likely that the activity of ACM resides in a complex of laminin with heparan sulphate proteoglycan^{20,21}

A possible explanation for the failure of E11 Thy-1⁺ neurones to extend neurites *in vitro* is that as RGC mature, they become intrinsically unable to regenerate their axons. However, previous studies have demonstrated that rat RGC, which had extended axons to their retino-receptive targets in the brain, are able to regrow neurites when cultured on some substrates^{22,23}. Moreover, after optic nerve transection in adult rats, RGC have been shown to regrow axons into sciatic nerve grafts²⁴. These observations on mammalian RGC suggested that E11 chick RGC could extend neurites *in vitro* if given the appropriate

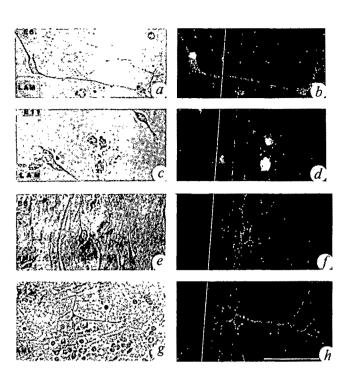

Fig. 2 Effect of maturation on neurite extension by Thy-1⁺ retinal neurones grown on laminin and astrocytes. The cells were photographed using phase-contrast (a, c, e, g) or fluorescein (b, d, f, h) optics. Note that while E6 Thy-1⁺ neurones extend neurites on laminin (LAM) (a, b) and type-1 astrocytes (AML) (e, f), E11 Thy-1⁺ neurones fail to extend neurites on LAM (c, d) but do so on AML (g, h). All Thy-1⁺ process-bearing cells also stained with a monoclonal antibody (RT97) against neurofilaments (not shown). On AML (e-h) Thy-1⁺ cells assumed a more complex morphology than on laminin (a-d). Scale bar, 50 μ m.

Methods. Retinas were separated from choroidal and scleral tissue, dissected free of pigment epithelium and incubated at 37 °C for 20 min in Ca²⁺, Mg²⁺-free Earle's balanced salts (BSS) plus 0.1% trypsin and bovine serum albumin (BSA, 3 mg ml⁻¹; Sigma). Tissue was removed and resuspended in BSS plus soybean trypsin inhibitor (SBT1, 0.52 mg ml⁻¹; Sigma), DNase (0.04 mg ml⁻¹; Sigma) and BSA and dissociated by repetitive trituration in a wide-bore Pasteur pipette to give a single-cell suspension. Homogeneous cultures of rat type-1 astrocytes (AML) were prepared from neonatal cerebral cortex tissue as described previously²⁸. (Rat, rather than chick astrocytes were used as a growth substrate as immature chick astrocytes do not express the astrocyte-specific marker GFAP³⁸ and could not, therefore, be reliably monitored for their purity in vitro. Preliminary experiments established that the neurite-outgrowth-promoting activity of rat type-I astrocytes was as effective with chick neurones as previously shown for rat neurones²⁵.) Laminin substrate was prepared by incubating PL-coated glass coverslips at room temperature for 2 h in a solution of laminin (10 µg ml⁻¹; BRL) in serum-free culture medium (see below), followed by two brief rinses in medium. Retinal cells (50,000) were plated onto pre-coated glass coverslips in Falcon multi-well plates and grown in Ham's F12 medium (Flow) supplemented with 0.5% fetal calf serum and the following (µg ml-100 BSA, 5 insulin, 100 transferrin, 6 progesterone, 16.1 putrescine and 5.6 selenium, as modified from Bottenstein and Sato³⁹. All cultures were incubated for 48 h at 37 °C in a humidified atmosphere of 5% CO₂, 95% air. Living cultures were labelled with monoclonal anti-Thy-1 antibody (ascites fluid diluted 1:100) for 30 min at room temperature, followed by biotinylated anti-mouse immunoglobulin and fluorescein-streptavidin as described in Fig. 1 legend, except that incubation times were shortened to 30 min. Coverslips were fixed in 95% ethanol/5% acetic acid, mounted in glycerol/DABCO and labelled cells photographed as described in Fig. 1 legend.

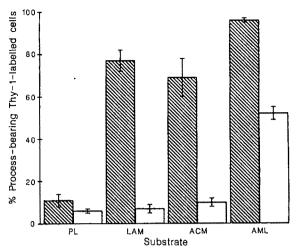

Fig. 3 Effect of laminin (LAM), ACM and AML on neurite outgrowth by E6 (SS) and E11 (□) Thy-1⁺ neurones. Most of E6 Thy-1+ neurones extended neurites on LAM, ACM and AML while only AML induced neurite outgrowth by E11 Thy-1+ neurones. Retinal cells (50,000) from E6 or E11 retinas were plated onto glass coverslips pre-coated with PL, LAM or AML as described in Fig. 2 legend. In experiments using ACM as substrate (PLbinding material from astrocyte-conditioned medium), PL-coated coverslips were incubated overnight in culture medium conditioned over confluent monolayers of rat astrocytes for at least 24 h. After 48 h of culture, coverslips were labelled with anti-Thy-1 antibody as described in Fig. 2 legend. After fixation the cultures were co-labelled with RT97 (ascites fluid, 1:200) for 30 min at room temperature followed by rhodamine-conjugated anti-mouse immunoglobulin 1:100; Cappell). Coverslips were then washed and mounted as described in Fig. 2 legend. The total number of Thy-1⁺ cells per coverslip (≥50 cells), and the number with Thy-1⁺/RT97⁺ processes longer than 3 cell diameters, were counted. The results shown are the mean (±s.e.m.) of at least four separate experiments. At E6 a significant difference (Student's t-test) was found between PL and LAM (P < 0.0006), PL and ACM (P < 0.04) and between PL and AML (P<0.0001). At E11 a significant difference was found between PL and AML (P < 0.0004) but no significant difference was found between PL and LAM (P > 0.7)or between PL and ACM (P>0.2).

substrate. We therefore cultured retinal cells on monolayers of purified rat brain astrocytes (AML) which consisted of >95% glial fibrillary acidic protein-positive (GFAP⁺) type-1 astrocytes with a flat fibroblast-like morphology¹⁹. Such cells are known^{25,26} to provide a highly adhesive substrate for the growth of neurites in vitro and possibly also in vivo^{27,28}. We found that on AML the majority of Thy-1⁺ neurones in cultures of both E6 and E11 retina extended long neurites (Figs 2e-h, 3). Moreover, the neurite-promoting effect of AML on Thy-1⁺ neurones seemed to depend on direct contact with the astrocytes and not on astrocyte-derived soluble factors, as the effect was abolished in co-cultures arranged to prevent contact²⁵.

An alternative explanation for our findings is that during maturation, RGC surface receptors for laminin are lost or modified. However, evidence against receptor down-regulation is provided by our experiments (not shown) with a monoclonal antibody, JG22, which is specific for a cell surface receptor complex that binds both laminin and fibronectin^{29,30}. When trypsinized suspensions of E6 and E11 retina were allowed to settle onto coverslips and labelled with JG22 antibody, over 80% of cells in the larger size range (>10 µm diameter), corresponding to the majority of Thy-1⁺ cells on duplicate coverslips, were JG22⁺ at both ages, and labelling was more intense at E11 than at E6. When cultured on a substrate permissive for neurite outgrowth, RGC cell bodies, neurites and growth cones were JG22⁺. Also, in immunostained tissue sections taken from the retinas of E6 and E11 chicks (not shown) RGC axons in the optic fibre layer and the optic nerve head were intensely JG22⁺

along their entire length. Therefore, these findings raise the possibility that the receptor complex on E11 RGC is modified so as to reduce its affinity for laminin. Alternatively, transduction mechanisms within the cells may be uncoupled from the binding event.

What is the nature of the molecules on the astrocyte surface which promote neurite outgrowth? Whereas brain astrocytes can produce laminin in vitro³¹, the failure of either pure laminin or ACM substrate to evoke a response from E11 RGC argues that the neurite-promoting activity of the astrocyte cell surface resides in either a modified form of laminin not represented in ACM, or in an entirely different molecule. Evidence against the first possibility was provided by further experiments (not shown) with JG22 antibody: whereas the antibody blocked most neurite outgrowth by E6 RGC on either laminin or ACM substrate, it failed to inhibit outgrowth by E6 or E11 RGC on AML. It may be that the neurite-promoting molecule on the astrocyte surface is one of the cell adhesion molecules previously shown to influence neurone-astrocyte interactions^{32,33}.

From days 6 to 11 of incubation in the chick embryo, maturation of the optic pathway is characterized by the transition from a predominantly retinal to a tectal phase of RGC axon outgrowth¹³. It is possible, therefore, that the change in substrate requirements for growth in vitro reflects a response by RGC in vivo to changes in the composition of the substrate that their growth cones encounter as they traverse the optic pathway. Such changes could be regulated by temporal or spatial mechanisms. Evidence for the former has come from an immunohistochemical survey with anti-laminin antibodies of the embryonic chick optic pathway throughout development. We have shown, using a sensitive immunohistochemical method, that in addition to its presence in basement membranes at the inner limiting membrane and pigment epithelium³⁴, laminin is also expressed by neuroepithelial cells throughout the optic pathway, within the retina, optic fissure, stalk and tectum during the earliest stages of maturation (between E3 and E7), becoming restricted to basement membrane locations only after E8 (ref. 35 and J.C., J.F.B. and J.W., unpublished observations). These findings suggest that laminin is a component of the physiological substrate for RGC axon extension during the earliest phase of outgrowth in vivo, and provide an explanation for our observations of the response of E6 RGC to growth on laminin in vitro. The mechanism whereby the maturation of RGC is accompanied by a loss of response to laminin remains to be elucidated. The fact that the timing of this change coincides with the arrival of the bulk of optic axons at the tectum raises the possibility that an alteration in the substrate requirements for axon extension may be one of the consequences of the transition from a target-independent to a target-dependent phase of RGC maturation. Future experiments should allow us to test whether optic tectum-derived factors can influence the substrate requirements in vitro for neurite outgrowth by RGC as a function of maturation.

We thank D. Gottlieb for supplying JG22 antibody, John Wood for RT97 antibody and Martin Raff and other members of the Neuroimmunology Group for helpful suggestions.

Chloride and potassium channels in cystic fibrosis airway epithelia

Michael J. Welsh & Carole M. Liedtke

Laboratory of Epithelial Transport and Pulmonary Division, Department of Internal Medicine, University of Iowa College of Medicine, Iowa City, Iowa 52242, USA and the Cystic Fibrosis Center, Department of Pediatrics, Developmental Genetics and Anatomy, School of Medicine, Case Western Reserve University, Cleveland, Ohio 44106, USA

Cystic fibrosis, the most common lethal genetic disease in Caucasians, is characterized by a decreased permeability in sweat gland duct and airway epithelia. In sweat duct epithelium, a decreased Cl permeability accounts for the abnormally increased salt content of sweat1. In airway epithelia a decreased Cl permeability, and possibly increased sodium absorption, may account for the abnormal respiratory tract fluid^{2,3}. The Cl impermeability has been localized to the apical membrane of cystic fibrosis airway epithelial cells4. The finding that hormonally regulated Cl channels make the apical membrane CI permeable in normal airway epithelial cells suggested abnormal Cl channel function in cystic fibrosis. Here we report that excised, cell-free patches of membrane from cystic fibrosis epithelial cells contain Cl channels that have the same conductive properties as CI channels from normal cells. However, Cl channels from cystic fibrosis cells did not open when they were attached to the cell. These findings suggest defective regulation of Cl channels in cystic fibrosis epithelia; to begin to address this issue, we performed two studies. First, we found that isoprenaline, which stimulates Cl secretion, increases cellular levels of cyclic AMP in a similar manner in cystic fibrosis and non-cystic fibrosis epithelial cells. Second, we show that adrenergic agonists open calcium-activated potassium channels, indirectly suggesting that calcium-dependent stimulus-response coupling is intact in cystic fibrosis. These data suggest defective regulation of Cl channels at a site distal to cAMP accumulation.

Figure 1 shows a model of the cellular mechanism of Cl⁻secretion by airway epithelia⁶. Chloride enters the cell at the basolateral membrane coupled to Na⁺ on an electrically neutral co-transport process. Chloride then leaves the cell across a Cl⁻-conductive apical membrane; regulation of the Cl⁻ conductance determines, in part, the rate of transepithelial Cl⁻ secretion. Chloride channels produce the apical Cl conductance. Using the patch-clamp technique, we recently described a Cl channel from the apical membrane of normal human airway epithelial cells which had properties different from those of previously described Cl channels^{5,8}. The ion selectivity, response to inhibitors and activation by secretagogues indicate that this Cl

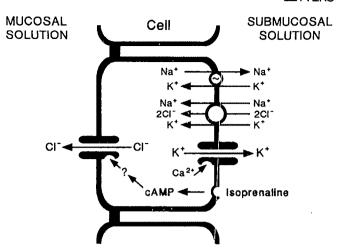

Fig. 1 Model of the cellular mechanism of Cl⁻ secretion. Chloride enters at the basolateral membrane via a NaKCl co-transport process that is inhibited by loop diuretics. The energy to drive intracellular Cl⁻ accumulation above electrochemical equilibrium comes from the movement of Na⁺ down its electrochemical gradient. A low intracellular Na⁺ concentration is maintained by the ouabain-inhibitable (Na⁺ + K⁺)ATPase. Potassium that enters the cell in exchange for Na⁺ and coupled to Cl⁻, exits from the cell across the basolateral membrane through Ca²⁺-regulated K⁺ channels. Chloride leaves the cell across the apical membrane through Cl⁻ channels.

channel is responsible for the apical Cl⁻ conductance in airway epithelia.

The decreased Cl⁻ permeability in cystic fibrosis (CF) apical membranes is therefore most probably due to abnormal Cl⁻ channel function. There are several possible ways to explain such a defect: it might result from an absence of Cl⁻ channels (such as faulty insertion into the cell membrane), from the presence of Cl⁻ channels with abnormal conductive or ion-selective properties, from inhibition of the Cl⁻ channels, or from faulty regulation of apical membrane Cl⁻ channels.

To address these possibilities, we examined single-channel currents in primary cultures of CF airway epithelial cells, to look for Cl⁻ channels with the same properties as those observed in non-CF cells. In excised cell-free patches of membrane from four preparations, we observed single-channel currents that were characteristic of Cl⁻ channels. Figure 2a shows tracings of the

current from an excised Cl⁻ channel, and Fig. 2b shows the single-channel current voltage (I-V) relation of that same channel. Figure 2b also shows that cation substitutions did not alter the I-V relation. In six patches the channel was exposed to cation gradients, either Na⁺ or K⁺, without a shift in reversal potential. In contrast, Fig. 2c shows that a Cl⁻ concentration gradient shifted the reversal potential, as expected for a channel that is selective for Cl⁻ over Na⁺. Calculation of the relative Cl⁻ to Na⁺ permeability, P(Cl/Na), from the Goldman-Hodgkin-Katz equation yielded a value of 6.5 ± 0.4 (mean \pm s.e.m., n=3). The I-V relation of a Cl⁻ channel from a non-CF cell is shown in Fig. 2b for comparison.

Several features indicate that in excised patches these channels are identical to non-CF Cl⁻ channels that are responsible for the apical Cl⁻ conductance and Cl⁻ secretion⁵. First, the conductance of the channel $(26\pm2 \text{ pS} \text{ measured at } 0 \text{ mV} \text{ with } 100 \text{ mV})$

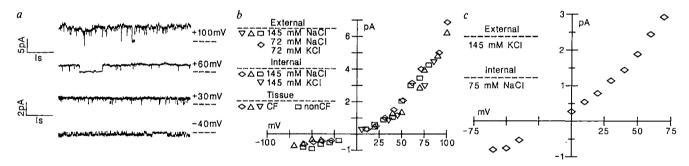

Fig. 2 Tracings and current-voltage relations of Cl⁻ channels. a, Single Cl⁻ channel currents recorded from an excised, inside-out patch at four holding voltages. Outward currents are shown as upward deflections. The current level when the channel is closed is given by the dashed line. The tracing shows substantial open-channel noise, a characteristic of the Cl⁻ channel. This channel was open most of the time and did not show marked voltage dependence of kinetics. The external (pipette) solution contained 72 mM NaCl, 72 mM KCl and 1 mM Ca²⁺ and the internal (bath) solution contained 145 mM NaCl and 5 mM EGTA (estimated Ca²⁺ concentration <1 nM). b, Current-voltage relation obtained from the channel shown in Fig. 2a (\diamondsuit); I-V relation with symmetrical 145 mM NaCl solutions (\triangle); and the relation when the external solution was 145 mM NaCl and internal solution was 145 mM KCl (∇). For comparison the I-V relation of a Cl⁻ channel obtained from non-CF cells is shown (\square)⁵. There is some variability in the absolute conductance of Cl⁻ channels from non-CF cells, however, Cl⁻ channels from CF cells did not show any appreciable difference from non-CF channels. c, I-V relation with 145 mM KCl externally and 75 mm NaCl, 150 mM sucrose and 2.5 mM EGTA internally. The observed reversal potential, approximately -13 mV, is close to the value expected for the Cl⁻ activity gradient (-15.4 mV). In contrast, the cation gradients across the channel would predict either positive or very large negative values for K⁺- or Na⁺-selective channels, respectively. We identified this channel in 19 of 198 successfully excised patches from CF cells, whereas under similar conditions it was observed in 2-10% of successfully excised patches from non-CF cells⁵. Methods. The technique used for constructing pipettes and seal formation 5,12 is similar to that described by Hamill et al.⁷. Either a Dagan Model 8900 or a List EPC 7 amplifier was used for voltage clamping and current amplifica

Model 8900 or a List EPC 7 amplifier was used for voltage clamping and current amplification. For some studies, currents were filtered (500-750 Hz) by an 8-pole Bessel filter, viewed on an oscilloscope and recorded on a strip-chart recorder. The 90% rise-time for a 2-cm deflection on the recorder was 3.5 mS. Results were analysed by hand. For other studies currents were filtered at 1 kHz and recorded (500 μ s sampling rate) and analysed with a laboratory computer system (Indec Systems). Pipette resistance was 2.5-10 M Ω and seal resistance was 3-30 G Ω . During seal formation and when recording in the cell-attached mode, bath solution contained (in mM): 140 NaCl, 1.2 CaCl₂, 1.2 MgCl₂ and 10 HEPES buffered with KOH (5 mM). All bath and pipette solutions contained 10 mM HEPES buffered to pH7.2, except the standard bath solution at pH7.4. Junction potentials that developed in the presence of asymmetrical salt solutions were directly measured with a 3 M KCl electrode and corrected for. Experiments were performed at room temperature (21-23 °C). Cells were studied 4 h to 3 days after plating. Voltages are reported in reference to the external surface of the membrane and outward (+) current refers to the flow of cations from internal to external surface of the patch, or anion flow in the opposite direction.

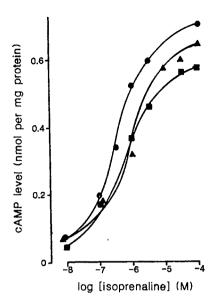

Fig. 3 Effect of isoprenaline on cellular levels of cAMP. Source of cells: ●, CF tracheal epithelium; ■, CF nasal epithelium; ▲, non-CF tracheal epithelium. To measure cellular concentrations of cAMP, the culture medium was replaced with Hank's balanced saline solution (HBSS) containing 10 mM HEPES pH 7.4 and (−)isoprenaline at varying concentrations. Isoprenaline was prepared and diluted in the same buffered salt solution. After incubation for 10 min at 37 °C, the medium was removed and cellular cAMP was released using dilute HCl (0.1 M). Cyclic AMP radioimmunoassay kits (Amersham) were used for measurement of cAMP levels. The cells were treated with 1 M NaOH to dissolve cellular protein which was measured according to the method of Lowry et al. 13, using bovine serum albumin as the standard. Cyclic AMP levels were calculated as nmol cAMP per mg protein.

symmetrical 145 mM Cl⁻, n=10) is the same as in normal humans. Second, the strong rectification of the I-V relation, even with symmetrical bathing solutions, is quite characteristic. Third, the selectivity for Cl⁻ over cations is similar. Fourth, there is an appreciable amount of open-channel noise (Fig. 2a) which we find characteristic of Cl⁻ channels from normal human cells. Fifth, the Cl⁻ channel blocker diphenylamine 2-carboxylate (1 mM) decreased single-channel current to 53% of control values (at +60 mV, n=1, data not shown), a response similar to that found in non-CF Cl⁻ channels. Sixth, the channel in CF and non-CF cells was not strongly voltage-gated, nor was it acutely regulated by internal Ca²⁺ concentration under these conditions; there was no apparent effect on excised channels of changing from 1 mM internal Ca²⁺ to less than 1 nM Ca²⁺ (5 mM EGTA and nominal Ca²⁺).

Although excised patches from CF cells had Cl channels with conductive and kinetic properties identical to those observed in Cl channels from non-CF cells, we never observed a Cl channel in the cell-attached recording mode, even though we looked for its activity following each successful seal and treated the cells with isoprenaline (5 μ M), adrenaline (1 μ M), 8-bromo-cAMP (100 µM) and/or forskolin (100 µM). In non-CF tracheal epithelial cells⁵ the Cl⁻ channel was observed in the cell-attached mode in 58% of 40 patches that contained Cl channels. In contrast, in CF cells the Cl channel was not observed cell-attached in the 19 patches that were shown to contain Cl⁻ channels after excision (P < 0.001 by χ^2 analysis). These findings suggest that Cl impermeability of the apical membrane in CF does not result from the complete absence of Cl channels or from the presence of Cl channels with abnormal conductive properties. Rather, they suggest that abnormal regulation of Cl channels produces the decreased Cl permeability8

To investigate regulation of ion transport in CF epithelial cells, two studies were performed. First, we measured intra-

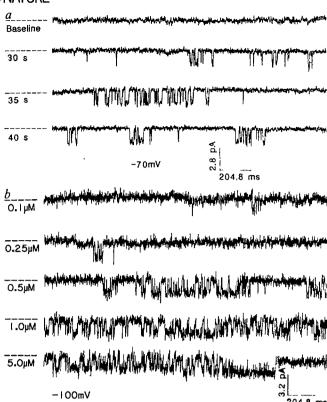

Fig. 4 Potassium channels in CF cells. a, Effect of adrenaline on K⁺-channel activity in a cell-attached patch. Sweeps were taken under baseline conditions and at the times indicated, following addition of adrenaline (1 μ M) to the bathing solution. The holding potential was -70 mV (membrane hyperpolarized). The pipette solution contained 72 mM KCl, 76 mM NaCl and 1 mM CaCl Downward deflections represent inward current. The dashed line indicates the current level when all channels are closed. b, Effect of internal Ca2+ on K+-channel activity in an excised, inside-out patch. Tracings were obtained from a single patch held at -100 mV The external (pipette) solution was 200 mM potassium glutamate and 5 mM MgCl₂; internal solution was 140 mM KCl. Internal Ca²⁺ concentrations indicated were achieved by buffering 5 mM EGTA with Ca²⁺ assuming a 1.5×10⁻⁷ M dissociation constant. Methods. Tracheas for cell culture were obtained from three patients at autopsy and nasal polyps were obtained from three patients at the time of polypectomy. Measurement of cAMP was made in cells from one trachea and nasal polyps from three patients, and electrophysiological measurements were made in cells from three tracheas and one culture of nasal polyps. The tissue was washed extensively with sterile HBSS containing (per ml) 100 U penicillin, 100 µg streptomycin, 50 µg tobramycin and 200 mg piperacillin, then incubated at 37 °C with antibiotics for 60 min. The wash and incubation cycles were carred out four times. The tissue was then incubated overnight with HBSS at 7 °C and the epithelium dissected free from the submucosal tissue the next morning. Epithelial cells were isolated according to the method of Liedtke and Tandler¹⁴ with the following modification. Dissected surface epithelium was incubated with collagenase (135 U ml⁻¹), 2 mM EGTA, 2 mM Mg²⁺ and DNase (2 mg ml⁻¹). Dispersed epithelial cells were recovered by centrifugation, washed in sterile HBSS to remove chelators and enzymes, and suspended in culture medium consisting of a 1:1 (v/v) mixture of Ham's F12 and Dulbecco's modified Eagle's medium containing antibiotics as indicated above. Total cell recovery ranged from 38×10^6 to 63×10^6 cells. Cell viability was 95-98% as assessed by fluorescent staining with acridine orange and ethidium bromide. An aliquot of the cell suspension was flown to M.J.W. for studies on single ion channels. The remaining cells were diluted in culture medium supplemented with 5 μM hydrocortisone, 5% fetal calf serum and (per ml) 1 μg insulin, 1 µg transferrin, 4 µg fibronectin and 1 µg epidermal growth factor. For cAMP assays, cells were plated onto collagen-coated plastic culture dishes at 500,000 cm⁻². For electrophysiological studies, cells were seeded at 5,000-20,000 cm⁻². Cultures were maintained at 37 °C in a humidified 5% CO₂ atmosphere

cellular levels of cAMP. Although the intracellular factors that directly regulate the Cl channel are unknown, circumstantial evidence suggests that cAMP is involved; many secretagogues. including β -adrenergic agonists, increase intracellular levels of cAMP and exogenous addition of cAMP stimulates Cl⁻ secretion^{9,10}. Figure 3 shows that the β -adrenergic agonist (-)isoprenaline caused a similar dose-dependent increase in cAMP levels in cultured CF and non-CF epithelial cells. The concentration of isoprenaline required to produce a halfmaximal increase in cAMP (EC₅₀) was $0.4\pm0.1~\mu\text{M}$ in non-CF tracheal epithelium (n = 3), $0.5 \pm 0.1 \mu M$ in CF nasal epithelium (n=3) and $0.4 \,\mu\text{M}$ in CF tracheal epithelium (n=1). The increase in cAMP was blocked by (\pm) propranolol, a β adrenergic antagonist, indicating that isoprenaline interacts with B-adrenergic receptors (data not shown). Both CF and non-CF cells showed a similar rank-order of potency for adrenergic agonists: isoprenaline > adrenaline > noradrenaline. Similar results have been obtained in the secretory coil of CF and non-CF sweat glands: isoprenaline produced identical increases in cellular levels of cAMP¹¹. Thus, if cAMP regulates the Cl⁻ channel, the defect in CF would probably lie somewhere distal to the production of cAMP.

470

Second, to further examine stimulus-response coupling in airway epithelia, we studied the K+ channels responsible for the basolateral K⁺ conductance¹². Stimulation of Cl⁻ secretion activates both apical Cl⁻ channels and basolateral K⁺ channels. Activation of K⁺ channels results from an increase in intracellular Ca2+ concentration. CF cells contained K+ channels with the same conductive and ion-selective properties as cells obtained from non-CF humans and dogs. Figure 4a shows that addition of adrenaline to the bathing solution activated a cellattached K⁺ channel. A similar response was observed on three occasions using isoprenaline and in cells from three of the four preparations studied. To show that the channel was regulated by the internal Ca²⁺ concentration, we used inside-out, cell-free patches as shown in Fig. 4b. Increasing the concentration of Ca²⁺ bathing the cytosolic surface of the patch increased the probability of finding the K⁺ channel open. The same response was observed in cells from all four patients. This apparently normal regulation of the Ca2+-activated K+ channel suggests that the metabolic steps between hormone binding and regulation of the K⁺ channel (that is, regulation of intracellular Ca²⁺ concentration) are intact in CF.

In conclusion, these results suggest that CF epithelial cells contain the same apical Cl- channel as non-CF cells. However, the channel does not open when attached to the cell. Thus, the data suggest that the apical membrane is Cl impermeable because of abnormal regulation of the Cl channel. However, the data also suggest that β -adrenergic agonists bind to their receptors, that cAMP accumulation is intact and that the K⁺ channel, which is involved in Ca-dependent stimulus-response coupling, is activated normally. Thus, we speculate that the Cl impermeability of CF epithelia results from a defect in the metabolism of some intracellular mediator, the presence of an intracellular inhibitor of the channel, or an abnormal regulatory site on the Cl channel itself.

We thank Phil Karp, Timothy R. Ruppert, Robin Wicks, Theresa Butwell and Vanessa Krumbholz for technical assistance. We especially thank the patients with cystic fibrosis and their families for allowing us to obtain the tissue required for these studies. This work was supported by grants from the NHLBI (HL-29851) and NIADDK (AM-27651), the Cystic Fibrosis Foundation (National organization and Rainbow Chapter) and the American Heart Association. M.J.W. is an Established Investigator of the American Heart Association.

Role of the HTLV-III/LAV envelope in syncytium formation and cytopathicity

Joseph Sodroski, Wei Chun Goh, Craig Rosen, Kathryn Campbell & William A. Haseltine*

Department of Pathology, Dana-Farber Cancer Institute, Harvard Medical School and * Department of Cancer Biology. Harvard School of Public Health, Boston, Massachusetts 02115, USA

Acquired immune deficiency syndrome (AIDS) is characterized by marked depletion of the T4⁺ helper subset of T cells¹⁻³. The aetiological agent of the disease, the human T-lymphotropic virus type III (HTLV-III)/lymphadenopathy-associated virus (LAV), specifically kills T4⁺ cells in vitro⁴⁻¹⁰. Part of this specificity for the T4+ population residues in the relative efficiency with which HTLV-III infects these cells, as a result of a specific interaction between the T4 molecule and the virus envelope glycoprotein 11-13. In addition, the cytotoxic consequences of HTLV-III replication are dependent on cell type, as certain lymphoid and myeloid cells can be productively infected without notable cytopathic effect 14,15. Here we investigate the basis for the specific cytotoxicity of the virus, and report that high-level expression of the HTLV-III envelope gene induces syncytia and concomitant cell death in T4+ cell lines but not in a B-lymphocyte line. Syncytium formation depends on the interaction of envelope-expressing cells with neighbouring cells bearing surface T4 molecules. These results explain, at least in part, the specific cytopathic effect of HTLV-III infec-

The investigation of the envelope gene as a determinant of HTLV-III cytopathic effect was motivated by recognition that the exterior glycoprotein of several enveloped viruses is responsible for syncytium formation and contributes to the cytotoxic effects of infection¹⁶⁻²³. Moreover, previous findings ruled out a direct cytopathic role for the proteins unique to HTLV-III, including those encoded by the sor, 3' orf and tat-III (transactivator) genes. Viruses deleted for either or both of the sor and 3' orf genes replicate in and kill T4+ cells^{24,25}. Moreover, T4⁺ cell lines that express constitutively a functional tat_{III} gene product are viable²⁶

To determine whether the HTLV-III envelope gene was involved in the induction of syncytia and cell death, plasmids were constructed that produced high levels of the envelope glycoprotein. The construction of such plasmids was made possible by the finding that expression of the envelope gene directed by the HTLV-III long terminal repeat (LTR) is dependent on two other HTLV-III genes, tat-III and art²⁶⁻²⁹. Accordingly, these two functions were supplied in the initial experiments. The presence of the tat-III gene was guaranteed by using cells that express constitutively the tat-III gene product (Jurkat-tat-III and Raji-tat-III)30. The art function was supplied by using plasmids that were designed to express both the art and env proteins simultaneously (pIIIenv3-1 and pIIIenv3-2; ref. 29) (Fig. 1).

The T4⁺ Jurkat-tat-III cell line³⁰ was used as a recipient in these experiments. The gp160 and gp120 HTLV-III envelope

For these experiments, ~10⁷ cells were transfected with 10 µg of each plasmid DNA using the DEAE-dextran technique³⁸. Immediately after transfection the cells were pelleted and incubated for 30 min at room temperature in 1 ml of medium containing a 1:200 dilution of monoclonal antibody OKT8, OKT4 or OKT4A (Ortho Pharmaceuticals). The cells were then suspended in 10 ml of fresh medium containing a 1:400 dilution of monoclonal antibody and incubated at 37 °C until the syncytia were counted. In subsequent experiments, the OKT4A antibody reduced syncytium formation by >90% at dilutions of 1:800. For patient antisera containing HTLV-III neutralizing activity (p982, 12-8, 91-1, Wy and Pe) as well as control patient sera (Ba, K.C. and McD.), transfected Jurkat-tat-III cells were grown in medium containing a 1:10 dilution of serum and syncytia counted as described below. Neutralizing activities of the p982, 12-8 and 91-1 sera were determined to be 1:64, 1:64 and 1:32, respectively, by David Ho and Martin Hirsch using methods described previously³⁴. Neutralizing activities of the Wy and Pe antisera were determined by Thomas Matthews and Dani Bolognesi to be 1:500 and 1:150, respectively, in their assay³⁶. Immediately after transfection of Raji-tat-III cells with the indicated plasmids, a threefold excess of untransfected cells of the type indicated was added to the culture. Values in parentheses represent the percentage of the added cells that were T4⁺, as estimated by indirect immunofluorescence¹¹. Syncytia for the Jurkat-tat-III and Raji-tat-III experiments were counted from the photographic prints to determine the number of syncytia. The values represent the mean of three independent experiments, with the range of values indicated. For the experiment using Jurkat cells, 10⁷ cells were aliquoted for counting at 72 h post-transfection. The values represent the mean (and range) of three independent experiments. The syncytia observed following transfection of the ptat-I and ptat-I+plenv3-FS1 DNAs contained

gene products³¹ were produced in these cells on transfection with either the pIIIenv3-1 or -2 plasmids (Fig. 2a, lanes 3, 4). The expression of these proteins was eliminated by either a frameshift mutation or a deletion in the region of the envelope gene that encodes the exterior glycoprotein (pIIIenv3-FS1 and -D1, Fig. 2a, lane 5; b, lane 4).

Marked syncytium formation was observed by 48 h after transfection of Jurkat-tat-III cultures with plasmids that express the envelope glycoprotein (Fig. 3b, c and Table 1a). In these experiments, at least 30-80-fold increases in syncytia were observed relative to control or mock-transfected cultures, representing 0.5-1% of transfected cells, a value consistent with the transient transfection frequency of human lymphoid cell lines (J.S. and

W.A.H., unpublished observations). Greater than 90% of the syncytia are unable to exclude vital dyes by 2 weeks after transfection, indicating the cytotoxic nature of the events accompanying syncytium formation (see, for example, Fig. 3h). The syncytium formation and cytopathic effect observed in experiments with the *env*-expression plasmids were indistinguishable from those seen following infection of Jurkat-tat-III-cells with HTLV-III (Fig. 3a).

Neither syncytium formation nor cell death was noted in cultures transfected with the plasmids containing mutations in *env* that prevent expression of the gp160 and gp120 proteins (Fig. 3d, Table 1a). However, both of these plasmids (pIIIenv3-FS1 and -D1) continued to express *art* gene function, as judged

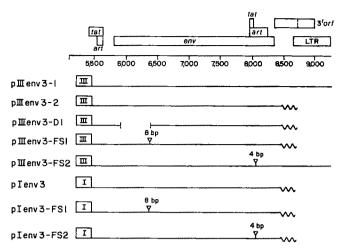

Fig. 1 Structure of the plasmids expressing art and env genes. The structure of the 3' half of the HTLV-III genome, based on the sequence of Ratner et al.32, is shown. The positions of the env gene, 3' orf gene and LTR are shown, together with the two coding exons of the tat-III and art genes in their respective reading frames. The position of a stop codon in the 3' orf gene of the parental proviral clone used in these studies, pHXBc2 (ref. 39), is denoted by a vertical broken line. In all the plasmids shown, LTR sequences from -167 to +80 for the HTLV-III LTR (boxes labelled III) or -353 to +326 of the HTLV-I LTR (boxes labelled I)⁴⁰ are located at nucleotide 5,496 of the sequence of Ratner et al. 32. The zig-zag lines represent signals for polyadenylation and splicing derived from the simian virus 40 early region⁴¹. The eight-nucleotide insertion (8 bp) in plasmids pIIIenv-3-FS1 and pIenv3-FS1 was introduced by digestion of either pIIIenv3-2 or pIenv3 with the restriction endonuclease Stul and insertion of 8-bp Xbal linkers before transfection of Escherichia coli. The construction of the other plasmids has been described previously²⁹. All plasmids were banded in CsCl before transfection.

by the ability of the plasmids to complement art-defective proviruses for gag or env gene expression²⁹.

Of special interest is the effect of another mutation present on plasmid pIIIenv3-FS2. The frameshift mutation of this plasmid interrupts the second coding exon of the art gene²⁹ and results in the replacement of the 104 carboxy-terminal envelope amino acids with 57 different amino acids³². The inability of the pIIIenv3-FS2 plasmid to synthesize env gene products can be complemented by co-transfection with plasmids expressing the art gene (pIIIenv3-D1 or -FS1) (Fig. 2a, lane 6; b, lanes 5-7). An altered env gene product capable of inducing syncytium formation and cell death was produced in this experiment (Table 1a, Fig. 3e, f), indicating that the 104 carboxy-terminal amino acids of the HTLV-III envelope are not required for these effects.

To determine whether expression of the HTLV-III envelope in the absence of tat-III or art functions is sufficient for syncytium formation and cytopathicity, plasmids containing the HTLV-I LTR 5' to the HTLV-III env gene were constructed (plenv3, plenv3-FS1 and plenv3-FS2; Fig. 1). One of these plasmids, plenv3-FS2, cannot encode a functional art product because of a frameshift mutation in the art gene coding sequences. plenv3-FS1 contains a frameshift mutation in the 5' portion of the env gene that encodes the exterior glycoprotein. These plasmids were transfected into Jurkat T-lymphocytes together with a plasmid (ptat-I) that expresses the trans-activator protein of HTLV-I33. The level of HTLV-III envelope expression and syncytium formation observed following transfection with plasmids plenv3 and plenv3-FS2 was lower than that observed using the trans-activated HTLV-III LTR as a promoter, but was at least 60-fold higher than that observed after transfection with plenv3-FS1 (Table 1b). The syncytia observed in this experiment were smaller (30-50 nuclei per syncytium) than those observed when the HTLV-III LTR was used as promoter (>200 nuclei per syncytium), but the viability of the syncytia was not appreciably different in the two experiments. We conclude that the HTLV-III tat-III and art genes are not required for either syncytium formation or cytopathicity consequent to env gene expression in T4⁺ lymphocytes.

To determine whether host cell factors might influence susceptibility to syncytium formation, a B-lymphocyte cell line that expresses constitutively the tat-III gene product, Raji-tat-III³⁰, was transfected with plasmids expressing the HTLV-III art and env genes. Raji-tat-III cells transfected with either pIIIenv3-1 or a combination of pIIIenv3-FS2 and pIIIenv3-D1 produced the gp160/120 envelope proteins at levels similar to those observed in Jurkat-tat-III cells (Fig. 2). Nonetheless, no syncytia or cytopathic effects were observed in the transfected Raji-tat-III cells (Table 1c).

To test whether the HTLV-III envelope glycoproteins synthesized in the Raji-tat-III cells were capable of inducing syncytia, the transfected Raji-tat-III cells were co-cultivated with various untransfected human lymphoid cell lines (Table 1c). Syncytia were observed within 72 h following addition of the human T-lymphocyte lines H9, Jurkat, C8166-45 and, to a lesser extent, HUT78 to the transfected Raji-tat-III cells. The syncytia formed in this experiment failed to exclude vital dyes within 7 days of their formation (data not shown). No syncytia were observed following addition of untransfected Raji or Raji-tat-III cells to the transfected cells. Thus, the transfected Raji-tat-III cells synthesized immunoprecipitable HTLV-III envelope proteins capable of inducing syncytia in a susceptible cell type.

Studies of animal retroviruses suggest that syncytium formation involves an interaction of virus-expressing cells with adjacent cells bearing receptors for the virus^{11,17-22}. The cells capable of forming syncytia following co-cultivation with Raji-tat-III

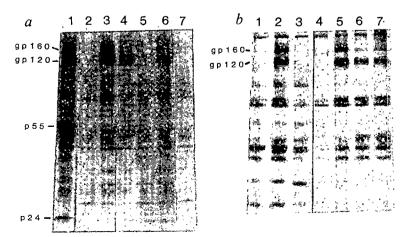

Fig. 2 Immunoprecipitation of transfected Jurkat-tat-III and Raji-tat-III cells. Jurkat-tat-III (a, lanes 1-7; b, lanes 4-7) or Raji-tat-III (b, lanes 1-3) cells were transfected by the DEAE-dextran procedure³⁷ using 10 µg of plasmid DNA; 48 h after transfection, cells were labelled with 35S-cysteine and cell lysates immunoprecipitated using an AIDS patient serum, RV119. The positions of the gp160 and gp120 env proteins and the p55 and p24 gag products are noted. Transfected plasmids were pHXBc2 (a, lane 1), pBR322 (a, lane 2), pIIIenv3-1 (a, lane 3), pIIIenv3-2 (lane 4), pIIIenv3-FS1 (lane 5), pIIIenv3-FS1 plus pIIIenv3-FS2 (lane 6), pIIIenv3-FS2 (a, lane 7 and b, lane 1), pIIIenv-D1 (b, lanes 3, 4), pIIIenv-D1 plus pIIIenv3-FS2 (b, lanes 2, 5-7). Transfected Jurkat-tat-III cells were incubated with monoclonal antibody OKT4 or OKT4A (b, lanes 6 and 7, respectively) as described in Table 1.

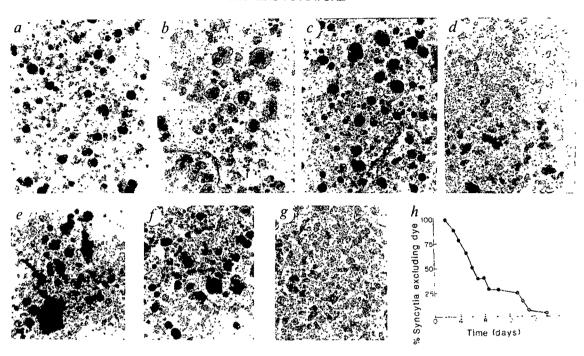

Fig. 3 Transfection of Jurkat-tat-III cells with plasmid DNAs. Approximately 10⁷ Jurkat-tat-III cells were transfected with 10 µg of plasmid DNA using the DEAE-dextran procedure³⁸, and the cells were photographed at various times after transfection (a-g, ×53). a, Jurkat-tat-III cells 5 days after transfection with plasmid pHXBc2, which generates replicating HTLV-III that kills the culture. b, c, Jurkat-tat-III cells 3 and 7 days, respectively, after transfection with plasmid pIIIenv3-1. The Jurkat-tat-III cells in d were transfected with plasmid pIIIenv3-FS1 7 days previously. e-g, Jurkat-tat-III cells 10 days after transfection with a combination of pIIIenv3-D1 and pIIIenv3-FS2, followed by treatment with OKT8, OKT4 and OKT4A, respectively. Treatment with monoclonal antibodies was as described in Table 1. h, Percentage of Jurkat-tat-III cells forming syncytia that exclude Trypan blue at various times after transfection with pIIIenv3-FS1 plus pIIIenv3-FS2. The transfected culture was fed every 3 days and aliquots removed for counting. Values were obtained by examining more than 200 random syncytia for uptake of Trypan blue. The curve shown is a typical experiment, with a maximum variation of 3 days in the time required for 50% dye exclusion in three separate experiments.

transfectants expressed the T4 molecule, which has been shown to be a component of the HTLV-III receptor¹¹⁻¹³. To examine the role of T-lymphocyte markers in syncytium induction by HTLV-III, Jurkat-tat-III cells were transfected simultaneously with two plasmids, pIIIenv3-D1 and pIIIenv3-FS2, the combination of which leads to high-level production of the env protein. The cells were then incubated with monoclonal antibodies directed against T8, T4 or T4A. Only the monoclonal antibody against T4A inhibited syncytium formation in the transfected Jurkat-tat-III cells (Fig. 3e-g, Table 1a). The absence of syncytia in the presence of the monoclonal antibody cannot be attributed to inhibition of env gene synthesis as levels of immunoprecipitable gp160/120 envelope proteins were similar regardless of the monoclonal antibody used for incubation (Fig. 2b, lanes 6, 7). The formation of syncytia following co-cultivation of envelopeexpressing Raji-tat-III cells with T4+ lymphocytes (Jurkat and H9) could also be inhibited by monoclonal antibodies against T4A but not by antibodies against T8 or T4 (Table 1c). Previous studies demonstrated that monoclonal antibodies against T4A but not against T4 or T8 could inhibit the interaction of the HTLV-III envelope with the T4 molecule¹³. These results suggest that the T4 epitope that interacts with the HTLV-III envelope is a necessary component in syncytium formation.

The ability of antisera from normal individuals and from HTLV-III-infected patients to inhibit syncytium formation by the HTLV-III envelope gene was assayed. The sera tested included some that previously were found to contain relatively high antibody titres that inactivate HTLV-III in virus neutralization tests³⁴⁻³⁶. All the patient sera tested contain antibodies to envelope glycoproteins as judged by radioimmune precipitation tests (not shown). None of the patient sera significantly inhibited syncytium formation by the HTLV-III envelope gene compared with control sera (Table 1).

The results presented here demonstrate that expression of the HTLV-III envelope results in marked syncytium formation and concomitant cell death indistinguishable from the effects of infection with HTLV-III itself. Syncytium formation does not occur in a cell line lacking the T4 molecule nor does it occur in the presence of antibodies known to interfere with the interaction between the HTLV-III envelope and T4. These results suggest that syncytium formation resulting from an interaction of the HTLV-III envelope with the T4 molecule is the basis for at least part of the specific cytotoxicity of HTLV-III for T4' cells. It is also likely that cell death will result from the expression of the HTLV-III envelope protein in an isolated cell that exhibits a high density of T4 surface antigen via an autofusion reaction that disrupts normal membrane function. The marked cytopathic effect of HTLV-III relative to most other retroviruses might be the consequence of several factors: the greater avidity of binding of the exterior glycoprotein for the receptor, efficient fusion activity of HTLV-III envelope domains, and high-level expression of virion components consequent to trans-activation.

Cells expressing the HTLV-III envelope glycoprotein, regardless of the level of expression of the T4 molecule, can serve to nucleate the formation of syncytia with uninfected cells that bear the T4 surface protein. This effect may contribute to the marked depletion of T4⁺lymphocytes observed in AIDS patients despite the small percentage of peripheral blood lymphocytes actively producing viral messages and protein at any given time³⁷.

The dependence of the cytopathic effect of HTLV-III on the interaction of the envelope glycoprotein with a T4 surface protein provides an explanation for the ability of the virus to infect but not kill cells that do not express high levels of the T4 molecule. Dalgleish et al. 11 observed that higher titres of anti-T4 antibodies are required to block infection by vesicular stomatitis

virus pseudotypes of HTLV-III than are necessary to inhibit syncytium formation, and suggested that more T4 molecules are required for syncytium formation than for infection by HTLV-

The antisera from HTLV-III-infected patients that we have tested exhibit at best slight inhibition of env gene-mediated syncytium formation or cytopathicity, even though they react with the envelope glycoprotein and are reported to inactivate virion infectivity³⁴⁻³⁶. Weiss *et al.*³⁵ also observed that most patient sera failed to inhibit syncytium formation. Inhibition of syncytium formation by antibodies is reported to be critical for the protective response to infection by other enveloped viruses²³. Failure to inhibit the fusion activity of the virus may account for the progression of HTLV-III-related diseases in the presence of antibodies reactive against the envelope glycoproteins, as cell-to-cell transmission of the virus may not be blocked in most patients.

Definition of both the binding and fusion domains of the HTLV-III envelope glycoprotein will be important for the development of strategies for protection against HTLV-III infection and consequent immune cell depletion.

We thank Drs George Shaw, Beatrice Hahn, Flossie Wong-Staal and Robert Gallo for the gift of the pHXBc2 provirus: Mary Fran McLane, Myron Essex, Dani Bolognesi, David Ho and Martin Hirsch for gifts of antisera; and Tanya Parks for manuscript preparation. A chromosomal rearrangement in a P. falciparum histidine-rich protein gene is associated with the knobless phenotype

Laura G. Pologe & Jeffrey V. Ravetch

DeWitt Wallace Research Laboratory, Memorial Sloan-Kettering Cancer Center, 1275 York Avenue, New York, New York 10021, USA

The significant morbidity and mortality associated with Plasmodium falciparum malaria results, in part, from the sequestration of parasitized erythrocytes in postcapillary venules, which may protect the parasite from splenic clearance^{1,2} and contribute to the pathogenesis of cerebral malaria³. This sequestration has been linked to the expression of parasite-induced knob structures on the surface of the infected erythrocyte which mediate the cytoadherence phenomenon^{4,5}. While knobs are necessary for cytoadherence, they are not sufficient, requiring both parasite- and host-encoded proteins⁶⁻¹⁰. Spontaneous mutants of P. falciparum have been isolated from in vitro cultures which lack the ability to express knobs and fail to cytoadhere11. A histidine-rich protein has been described which is associated with the knobby phenotype 12 and may be a constituent of the knob13. We now report the isolation of complementary DNA clones for a knob-associated histidine-rich protein (KAHRP) and demonstrate that in knobless mutants the gene for this protein has undergone a rearrangement, resulting in a deletion in the 3' coding sequence. Moreover, the chromosome to which the KAHRP gene maps is rearranged in these mutants, producing a telomeric location of the truncated gene. These observations explain the loss of expression of the messenger RNA and protein in such mutants and may explain the loss of the knob itself. The implications for the generation of spontaneous mutations in the parasite by this novel mechanism are discussed.

A cDNA library constructed to P. falciparum strain FcR-3 at the trophozoite stage was screened with a 1.8-kilobase (kb) EcoRI fragment derived from the histidine-rich protein gene of Plasmodium lophurae¹⁴ under reduced stringency (25% formamide, 10% dextran sulphate, 5×SSC, 7 mM Tris pH 7.6, 1 × Denhardt's buffer, 25 μg ml⁻¹ salmon sperm DNA at 40 °C; final wash = 0.1 × SSC, 0.1% SDS, 40 °C). cDNA clones which cross-hybridized with the avian gene were characterized further by restriction enzyme and Northern blot analysis to knobby (K⁺) and knobless (K⁻) RNA. Three overlapping cDNA clones (Fig. 1a) were characterized by DNA sequence analysis and shown to encode an open reading frame containing multiple polyhistidine sequences varying between 6 and 9 contiguous histidine residues (data not shown), a primary structure analogous to the P. lophurae gene¹⁴. These same clones were identified in the library using a cDNA probe to unique sequences in K⁺ mRNA constructed by subtractive hybridization¹⁵ between K⁺ and K⁻ clonal isolates. Northern blot analysis (Fig. 1b, c) demonstrated that stable mRNA transcripts of 4.2 kb accumulate in K+ but not K- isolates and are maximally expressed in trophozoites. Antibodies generated to the recombinant protein expressed in Escherichia coli recognize a protein (in FCR-3) of 80,000-90,000 relative molecular mass in K⁺ but not K⁻ isolates (Pologe and Ravetch, in preparation). This expression pattern is in agreement with the expression of a knob-associated histidine-rich protein described previously^{12,16}. Independent clonal derivatives of K⁺ parasites from a wide range of geographical isolates demonstrated expression of this RNA only in K+ isolates (see Fig. 1b). Thus, by virtue of its histidine-rich amino-acid sequence and expression in K+ and not K- isolates, these clones represent cDNA isolates for a KAHRP gene.

To investigate how the accumulation of stable transcripts for this gene has been lost in K isolates, DNA was isolated from K⁺ and K⁻ isolates, analysed with multiple restriction endonu-

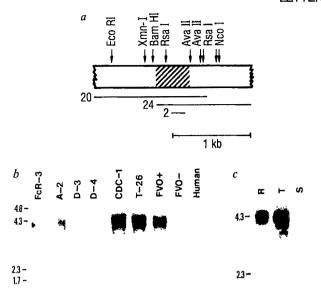

Fig. 1 a, Restriction map and cDNA clones for a knob-associated histidine-rich protein of P. falciparum. Cross-hatching, polyhistidine encoding sequences. Three overlapping cDNA clones are indicated with their numerical designation. b. Northern blot analysis of RNA isolated from multiple knobby (K+) and knobless (K-) isolates. Size markers are derived from P. falciparum and human rRNA sizes. FcR-3 is the non-clonal Gambian line established by Trager²⁵ and A-2 (K^+), D-3 (K^-) and D-4 (K^-) are clonal derivatives of that line²²; FVO⁺ is a K⁺ line cloned from a Vietnam isolate (ref. 26) and FVO⁻ a K⁻ clone derived from it²⁷; CDC-1 (ref. 28) is a Honduran isolate (K+) and T-26 is a Tanzanian isolate (K⁺). Two RNA species appear to be resolved for this KAHRP gene migrating at 4.1 and 4.2 kb. c, Stage specificity of KAHRP gene expression. R, rings; T, trophozoites; S, schizonts. The faint hybridization seen in the schizont lane may represent contamination of schizonts with trophozoites during synchronization. Methods. a, A cDNA library constructed in the PstI site of pUC-9 (ref. 29) was screened and the resulting clones characterized as described in the text. Overlapping clones were identified by restriction enzyme analysis and the fragment sizes verified by co-migration with genomic DNA. DNA sequence analysis was performed using the chemical degradation method of Maxam and Gilbert³ b, P. falciparum was grown in synchronous culture as described elsewhere 26 to obtain populations enriched for trophozoites (b) or rings and schizonts (c). 1 µg of total RNA was fractionated on agarose-formaldehyde gels, transferred to nitrocellulose and hybridized with nick-translated cDNA probes (specific activity 2×10^8 c.p.m. per μ g), under stringent conditions (50% formamide, 10% dextran sulphate, 5×SSC, 7 mM Tris pH 7.6, 1× Denhardt's, 25 μ g ml⁻¹ salmon sperm DNA; final wash = 0.1 × SSC, 0.1% SDS, 52 °C). These conditions were used for all stringent hybridization studies described. The 1.4-kb PstI insert of clone 20 was used in

cleases and probed with the cDNA clones illustrated in Fig. 1a. As shown in Fig. 2, the restriction fragments encoding this cDNA sequence are conserved in K⁺ parasites from two geographical isolates, as well as in clonal derivatives of these isolates. A single HindIII fragment of 10.5 kb is detected by these cDNA clones in K⁺ strains (lanes 1, 3), while two Xmn fragments of 8.1 and 3.4 kb are detected when clone 20 is used as a probe, as a result of an internal Xmn site in this cDNA clone (lanes 5, 6, 9). Similar studies on K⁺ isolates from Honduras (CDC-1) and Tanzania (T-26) reveal that the gene for this KAHRP is conserved (not shown). However, a DNA rearrangement has occurred in K⁻ isolates, resulting in more rapidly migrating species. The HindIII fragment is 6.1 kb in D-4 and 7.2 kb in FVO⁻ (Fig.

b and the 250-base-pair (bp) PstI insert of clone 2 for c.

2, lanes 2, 4). Similarly, the 5' Xmn fragment in FVO is unrearranged, while the 3' fragment, encoding the polyhistidine sequences, now migrates as a diffuse band of 2.3 ± 0.25 kb (Fig. 2. lane 10), K⁻ isolates D-3 and D-4 have lost the 5' Xmn site. resulting in a single rearranged Xmn fragment of 5.2 kb (Fig. 2, lanes 7, 8). This rearrangement has resulted in a deletion of DNA sequences corresponding to the 3' coding sequence of this gene. Restriction enzyme mapping of the strains shown in Fig. 2 with EcoRI, BamHI, XmnI, AvaII and HindIII, singly and in combination, using probes derived from both the 5' and 3' sequences of the KAHRP gene, demonstrated that the breakpoint of the deletion in different K- isolates varies by several hundred nucleotides. For clones D-3 and D-4, derived from FcR-3, the deletion breakpoint results in the loss of all histidineencoding sequences, while in FVO-, derived from a Vietnam isolate, the breakpoint retains polyhistidine sequences (see Fig. 3c). The rearranged DNA fragment observed in these K⁻ isolates migrates as a diffuse band (Fig. 2, lanes 2, 4, 7, 8, 10), implying that the DNA fragment that is generated varies in length in the different K-isolates. In addition, our restriction mapping studies suggest that a clustering of restriction enzyme cleavage sites has been introduced 3' of this gene in K⁻ isolates (data not shown).

The finding that a common restriction site had been introduced 3' of the rearranged gene in K isolates and the heterogeneity of the DNA fragment in these mutants suggested that the gene for the KAHRP in K isolates might have become relocated to the end of a chromosome. To test this hypothesis directly, DNA from FVO+ and FVO- parasites was subjected to Bal31 digestion for increasing lengths of time, then digested with the restriction enzyme HindIII. Southern blot analysis with the cDNA probe revealed that the 10.5-kb HindIII fragment is unaffected by Bal31 digestion in the K⁺ isolate (Fig. 3a), while the 7.2-kb HindIII fragment in the K isolate migrates as a 4.3-kb fragment after 30 min of Bal31 digestion (Fig. 3b). In other experiments, the 10.5-kb fragment remains undigested in this K⁺ isolate at 60 min while the DNA from the K⁻ isolate shows no detectable hybridization at 35 min (not shown). Similar analysis of A-2, D-3 and D-4 revealed increased susceptibility to Bal31 in the K⁻ isolates (data not shown). From the size of the truncated gene fragment in the K⁻ isolates, we can estimate that the rearrangement which has occurred in these mutants has relocated this gene within 2.5 kb of a telomere. Figure 3c summarizes findings regarding the structure of the KAHRP gene in K+ and K- isolates.

These observations suggested that there may be a chromosomal rearrangement in the K- isolates involving the KAHRP gene. P. falciparum chromosomes were separated by pulse-field gradient electrophoresis¹⁷ and hybridized with the cDNA clones isolated for the KAHRP (Fig. 4). The KAHRP gene maps to chromosome 2, which appears to be invariant in the K⁺ isolates used. However, the K⁻ isolates demonstrate a more rapidly migrating chromosome 2 which hybridizes with reduced intensity to the cDNA probe for this gene, due to the deletion within the KAHRP gene. As has been noted previously^{18,19}, P. falciparum isolates differ in their karyotype with respect to the size and number of chromosomes. For the clonal isolates FVO and FVO⁻, and also for the clonal isolates A-2 (K⁺), D-3 (K) and D-4 (K⁻), the only karyotypic difference observed is in chromosome 2. FcR-3, the non-clonal parent for A-2, D-3 and D-4, is perplexing in its karyotype when compared with its clonal isolates for chromosomes 1 and 4. The only chromosomal rearrangement, however, observed consistently for all K+ and K isolates, is seen for chromosome 2. Hybridization with the falciparum ribosomal RNA gene probe20 detected no difference in the clonal pairs (not shown), nor was there a difference when the gene for the glycophorin-binding protein GBP130 (ref. 21) was used. These results demonstrate that the DNA rearrangement found in K- isolates for the KAHRP gene is reflected at the chromosomal level, and may represent a large deletion from chromosome 2.

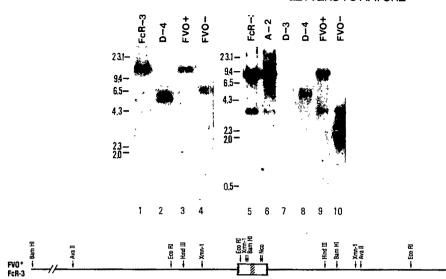

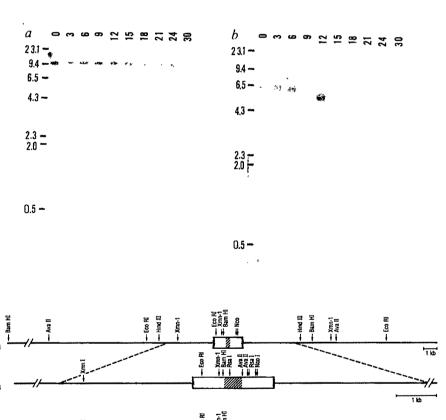

Fig. 2 Southern blot analysis³¹ of the KAHRP gene in DNA isolated from K+ and K- isolates. Lanes 1-4, HindIII digestions of DNA isolated from FcR-3 (lane 1), D-4 (lane 2), FVO+ (lane 3) and FVO- (lane 4) probed with a 5' PstI-Eco fragment of 250 bp derived from clone 20; lanes 5-10, XmnI digests of FcR-3 (lane 5), A-2 (lane 6), D-3 (lane 7), D-4 (lane 8), FVO+ (lane 9) and FVO (lane 10) probed with the Pstl insert of clone 20. Under the stringent conditions of hybridization and washing used, only one hybridizing fragment is detected for HindIII and two fragments for Xmn, as expected for K+ DNA. The genomic restriction map for this KAHRP gene is presented below the autoradiogram of the Southern blot. The cloned and sequenced region of the gene is indicated by the open box; hatching indicates the histidine-encoding sequences.

Fig. 3 a, b, Bal31 digestion of the KAHRP gene in K⁺ and K⁻ isolates. Numbers at the top of each lane refer to time in minutes. c, Summary of restriction maps of the KAHRP in K⁺ and K⁻ isolates. The breakpoints in FVO⁻, D-3 and D-4 are approximate, mapping to within the BamHI-AvaII fragment for FVO and the Xmn-EcoRI fragment for D-3 and D-4. The solid bar at the end of the maps for the K isolates indicates the end of a chromosome, as determined by the Bal31 experiments described above. Hatching indicates polyhistidine-encoding sequence.

Methods, a, b, FVO+ (a) and FVO- (b) DNA was obtained from these isolates as described elsewhere³², and digested with Bal31 according to the manufacturer's (NEB) specifications in a reaction containing 5 µg DNA, 1 U Bal31 in a total reaction volume of 175 µl. At the indicated time points, aliquots were brought to 20 mM EGTA, heated to 70 °C for 5 min and ethanol-precipitated. The DNA samples were digested with HindIII, fractionated on 1% agarose, Tris-acetate EDTA gels and transfer-red as described previously³¹. Hybridization under stringent conditions was performed using a 250-bp Pst-EcoRI fragment derived from clone 20 (see Fig. 1a). The rate of precession of the Bal31 was determined to be 80 bp min-1 based on digestion of λ DNA cut with HindIII under the conditions used for these experiments. The increased sensitivity of the gene in the K- isolate is seen. Analogous experiments performed with A-2 (K⁺), D-3 (K⁻) and D-4 (K-) revealed a similar pattern of increased Bal31 sensitivity (not shown) in the K- isolates. c, The restriction maps were generated using the enzymes indicated both singly and in combination. Sites within the cloned sequences were verified by DNA sequencing analysis.

These results demonstrate that the loss of expression of a KAHRP gene in knobless mutants is associated with a chromosomal rearrangement and deletion of part of the gene itself. The molecular mechanism which could account for the telomeric location for the truncated gene is under investigation. We do not know the extent of the deletion on chromosome 2, nor have we determined whether a reciprocal translocation involving telomeric exchange of DNA from chromosome 2 to some other

chromosome has occurred. The K⁻ phenotype occurs spontaneously in culture²², resulting in parasites which are otherwise wild type in their growth. If these mutants occur in vivo, they would presumably be selected against by splenic clearance, as has been shown²³. It is possible that K⁻ mutants accumulate in culture because of the absence of the negative selection exerted by the spleen in vivo. Thus, this chromosomal rearrangement may reflect a more general mechanism for mutation by the

Pulse-field gradient electrophoresis of P. falciparum chromosomes isolated from K+ and K- isolates. a, The ethidium bromide-stained gel pattern for various K⁺ and K⁻ isolates: b. an autoradiogram of the gel in a hybridized with a cDNA clone to the KAHRP gene.

Methods. Agarose blocks containing P. falciparum-infected erythrocytes were prepared as described previously^{17,18} using parasites grown in culture to parasitaemias of 10-20%. Chromosome separation was performed using the method of Schwartz and Cantor¹⁷ in 1% agarose, 0.5×TBE gels electrophoresed at 210 V for 22 h with a pulse frequency of 75 s in north-south and east-west directions. Following electrophoresis and staining in 1 µg ml⁻¹ of ethidium bromide, the gels were soaked in 0.25 M HCl for 1 h before transfer to nitrocellulose as described by Southern³¹. Hybridization under stringent conditions was performed using the nick-translated PstI fragment of clone 20. The strains are described in Fig. 1 legend. The numbering of the chromosomes is according to van der Ploeg et al.18, with chromosome 1 migrating at 700 kb and chromosome 6 at 2,000 kb.

parasite, resulting in the diverse karyotypes found in nature which could be of selective advantage in parasite survival. Although mechanistically this rearrangement may resemble the relocation of certain variable surface glycoprotein genes to telomeres in trypanosomes²⁴, the result of the K⁺ to K⁻ rearrangement is the loss of expression of a KAHRP gene. Analysis of these K⁺ to K⁻ mutations will provide an opportunity to determine the generality of chromosomal rearrangement in plasmodia and may yield insights into its mechanism.

Long-range restriction site mapping of mammalian genomic DNA

William R. A. Brown & Adrian P. Bird

MRC Mammalian Genome Unit, King's Buildings, West Mains Road, Edinburgh EH9 3JT, UK

Molecular analysis of many problems in genetics would be facilitated by the ability to construct restriction site maps of long stretches of genomic DNA and to directly place genes on these maps. Pulsed-field gradient gel electrophoresis allows measurement of the size of DNA fragments up to at least 2,000 kilobase pairs (kb) long^{1,2} and we have used this technique here to map sites for one class of infrequently cutting restriction enzyme over a total of 1,500 kb of mouse genomic DNA. The sites for these enzymes tend to be clustered in the genome. These clusters may correspond to the short stretches of C+G-rich unmethylated DNA³ often associated with mammalian genes.

To construct long-range maps of genomic DNA, enzymes are needed which cut the DNA infrequently. Sites for enzymes which have a 6-base-pair (bp) recognition sequence composed entirely of inter-strand C·G base pairs and which include one or more CpG dinucleotides (C·G enzymes) are rare in the mammalian genome because the DNA is low in G+C and because the CpG dinucleotide occurs at only 20-25% of the frequency expected from base composition⁴. In addition, the CpG dinucleotide is often methylated at cytosine and this inhibits cleavage by many C · G enzymes (see Table 1). It occurred to us that cleavable sites for methylation-sensitive C·G enzymes should not be distributed randomly with respect to one another in mammalian DNA but should be concentrated in short stretches of genomic DNA called HTF islands³; this is predicted because HTF islands are 65% C+G, show no CpG suppression, and are unmethylated (see Table 1). As the rare inter-island sites are likely to be methylated and therefore resistant to cleavage, our calculations suggest that almost all cleavable sites for methylation-sensitive $C \cdot G$ enzymes will be in HTF islands. Two lines of evidence which support this prediction are shown in Fig. 1. When DNA of high relative molecular mass (M_r) is restricted with Nael, SacII or SmaI and analysed by pulsed-field gradient gel electrophoresis, the DNA in each digest is distributed from ~50 kb up to the limit of resolution, which in this experiment was at 650 kb; about 30% of the DNA in the sample was above this limit. The SacII recognition sequence (Table 1) includes two CpG dinucleotides while the recognition sequences for NaeI and SmaI contain only one, yet all three enzymes gave a similar distribution of fragments. This result suggests that these enzymes are cutting in regions of the genome which show no CpG suppression. The observation that the double and single digests all contained a similar distribution of fragments suggests that the sites for the different enzymes are close to one another.

The standard strategy for mapping of restriction sites in genomic DNA involves a series of single and double enzyme digests, gel electrophoresis, blotting and hybridization. In general, however, this technique does not work where the sites for different enzymes are clustered. An alternative mapping strategy is to regard a particular HTF island as a landmark and to use pulsed-field gel electrophoresis to measure the distance from sites in that known island to the flanking sites located tens or hundreds of kilobases away. We used this strategy to map about three HTF islands in the mouse genome. Two of these islands were isolated at random from genomic DNA³ and one was from the 5' end of the dihydrofolate reductase gene (dhfr)^{5,6}. Although our results were obtained using mouse DNA, this approach can be applied to the DNA of other mammals.

The first region of the genome studied was that which flanks island HTF 9. This island was isolated from mouse DNA³ and is known to be associated with transcripts that occur in several mouse tissues (P. Lavia, unpublished results). Island HTF 9 has two sites each for the enzymes NarI, SacII and SmaI and three sites for NaeI (Fig. 2a). We digested high- M_r DNA with each of the four enzymes. To check that the digest was complete at the sites within the island, we restricted an aliquot of each digest with EcoRI and, after conventional agarose gel electrophoresis, analysed the products with a probe which encompasses island HTF 9 (Fig. 2b). As no trace of the full-sized EcoRI fragment remained in any of the double digests, we concluded that each enzyme could cleave completely within island HTF 9. This check on digestion is necessary for the construction of an unambiguous map because Nael, Narl and Sacll show site-dependent heterogeneity in their reaction rates (see ref. 7 and below). We then fractionated DNA that had been digested with the infrequently cutting enzymes by pulsed-field gradient gel electrophoresis, and analysed the fractionated DNA by filter hybridization. The probes in this experiment flank island HTF 9, thus the size of any hybridizing restriction fragment localizes the restriction site with respect to the HTF island. The gels were run at a shorter pulse time than those shown in Fig. 1 to allow better resolution of the fragments of lower M_r . Analysis with the left-hand probe (Fig. 2c) revealed two hybridizing fragments in the Nael digest: a small weakly hybridizing fragment and a larger fragment close to the unfractionated DNA. The latter fragment was more accurately sized on a gel run at a longer pulse time, and measured ~375 kb (not shown). In addition, there was a NarI fragment of 140 kb, two SacII fragments (30 and 140 kb) and a weakly hybridizing SmaI fragment (140 kb). On the right-hand side of the island (Fig. 2d) we observed a NaeI fragment of ~105 kb and NarI, SacII and SmaI fragments each ~40 kb long. Together these results yield the restriction site map around island HTF9 shown in Fig. 2e. This map also indicates the estimated error in the restriction fragment sizes which we have measured from our data. A limitation of this sort of map is that it may be incomplete. Because we are making measurements about a single point, we are unable to map distal to sites which are cut to completion. A striking feature of the analysis shown in Fig. 2c is the presence of more than one hybridizing fragment in the NaeI and SacII digests, which means that although island HTF 9 is completely cleaved by these enzymes, it is flanked on one side by NaeI and SacII sites which are only partially cleaved. These sites are clustered with sites for other tested enzymes, thus they would be expected to represent uncharacterized HTF islands. A possible explanation is that the site-dependent kinetics of cleavage by NaeI and SacII⁷ is responsible for the partial cleavage. The possibility cannot be excluded, however, that incomplete cleavage is due to partial methylation at these sites. Whatever the cause, partial cleavage increases the amount of data from the experiments.

We have used the same strategy to construct long-range maps around island HTF 12 (Fig. 3) and the HTF island at the 5' end of dhfr (Fig. 4). Two technical points were important in the construction of the long-range maps (Figs 3e, 4e). First, island HTF 12 lacks any NarI sites and so we were unable to locate the ends of the 375-kb NarI fragment including island HTF 12.

Fig. 1 Pulsed-field gradient gel electrophoresis of high- M_r mouse DNA restricted with either NaeII, SacII or SmaI alone or in combination. The M_r markers are multimers of phage λ -cI857 DNA produced by annealing the cohesive ends in free soution (λ_n) .

Methods. For the preparation of high-M, DNA, BALB/c mouse thymocytes were encapsulated in agarose beads at a concentration of 5×10^7 per ml of beads¹¹. The beads, washed free of paraffin, were washed once in phosphatebuffered saline (PBS), once in Tris-EDTA buffer (TE: 10 mM Tris-HCl, 1 mM EDTA pH 7.5), then the nuclei were lysed with detergent by resuspending them at a concentration of 2×10^7 cells ml⁻¹ in 10 mM Tris, 0.05 M EDTA, 1% SDS pH 8.0 at room temperature, The suspension became like a jelly, presumably because of the release of DNA from cells at the periphery of individual beads, and so was thoroughly mixed by forcing it through the 2-mm orifice of a pipette. When the suspension of beads had become less viscous, the beads were washed twice in TE buffer and once in an EDTA/lauroyl sarcosine buffer (NDS: 0.5 M EDTA, 10 mM Tris-HCl, 1% lauroyl sarcosine pH 9.5) and finally resuspended in 2 vol. NDS. Proteinase K (Boehringer) was added to a final concentration of 500 µg ml suspension of beads was incubated at 55 °C for 48 h. This digest was then made to 50% (v/v) with glycerol and stored at -20 °C. For restriction enzyme digestion of DNA, beads were washed in TE buffer (pH 7.8) and residual proteinase K inactivated with 5 mM phenylmethylsulphonyl fluoride. The beads were restricted as follows: 120 µl of beads restricted with 15 U of NaeI in a total volume of 150 µl; 240 µl of beads restricted with 62 U SacII in a total volume of 300 µl; and 360 µl of beads restricted with 70 U SmaI in a total volume of 450 µl. These samples were incubated at the recommended temperature for 5 h, then washed in TE. The slurry of washed beads containing SacII-digested DNA was divided into two equally sized aliquots, one of which was digested with 14 U Nael. The slurry of beads containing Smal-digested DNA was subdivided into three equally sized aliquots, one of which was further restricted with 14 U NaeI and another with 50 U SacII. The second round of digests continued for 5 h and the beads were then washed and loaded onto the electrophoresis slots. An aliquot of washed beads (120 µl) was incubated for 10 h in restriction buffer at 37 °C as a control for nonspecific nuclease degradation. These beads were washed and loaded into the right-most well. The pulsed-field gradient gel electrophoresis chamber was based on the design of Carle and Olson² but was modified to take a 20×20 cm gel plate. Construction details may be obtained from W.R.A.B. The DNA sample to be fractionated was loaded into a well of dimensions $8 \times 2 \times 6.5$ mm. The total depth of the agarose gel was 7.5 mm. The agarose (Sigma type II; Medium EEO) concentration was 1.5% (w/v) and the electrophoresis buffer was 0.5 × TAE (TAE is 0.04 M Tris-acetate, 0.001 M EDTA). The run time in this experiment was 26 h, buffer temperature 8 °C, pulse time 30 s.

Second, we were unable to completely cleave the NarI site in the dhfr HTF island and so could not place the NarI sites which flank this gene. The consistent failure to cleave this particular NarI site may be the result of either-site-dependent heterogeneity in the reaction rate of this enzyme or partial methylation at this site. The former explanation is strongly supported by our finding that the same NarI site in a genomic clone of dhfr is not cleaved completely even in the presence of a 40-fold excess of enzyme (data not shown).

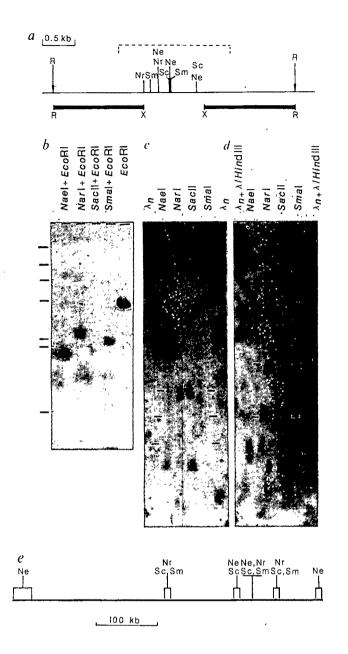

Fig. 2 Long-range mapping around island HTF9. a, Restriction site map of island HTF9. Ne, Nael; Nr, Narl; Sc, SacII; Sm, SmaI; X, XhoI; R, EcoRI. The probes used in the long-range mapping are indicated by the solid bars beneath the map. The broken line above the map indicates the extent of unmethylated DNA. b, Analysis of Nael, Narl, Sacli and Smal digestion at island HTF9. High-M, DNA that had either been restricted with Nael, Narl, Saell or Smal or incubated in restriction buffer without enzyme as described in Fig. 1 legend, was washed and restricted with EcoRI. Digests were fractionated by conventional 1% agarose gel electrophoresis and analysed using a 2.6-kb HindIII fragment including the whole island as a probe. The standards used in this gel were products of phage λ DNA restricted with HindIII. Some fragments are weaker than expected or undetectable on the blot because of their small size and also because low- M_r DNA fragments diffuse out of the beads during restriction and washing. The sizes of the restriction fragments seen in the digests were estimated as EcoRI 3.8 kb, NaeI+ EcoRI 1.8 kb, NarI+ EcoRI 2.5 kb, SacII+ EcoRI 1.8 kb and SmaI + EcoRI 2.2 kb. These values are consistent with each of the infrequently cutting enzymes cleaving at one or more of the respective sites in this island. c, Mapping to the left of island HTF 9. High-M, DNA restricted with Nael, Narl, Sacli or Smal was fractionated by pulsed-field gradient gel electrophoresis, transferred to GeneScreen Plus and analysed by hybridization using the left-hand Xhol-EcoRI fragment shown in a Conditions of electrophoresis: pulse time 22.5 s, run time 20 h, buffer temperature 18 °C; 300 V. d, Mapping to the right of island HTF 9. High-Mr DNA restricted and fractionated as described above was transferred to nitrocellulose and analysed by hybridization using the right-hand XhoI-EcoRI fragment shown in a. Conditions of electrophoresis: pulse time 8 4 s, run time 27 h, buffer temperature 8 °C, 300 V. The bars marked on the autoradiographs in c and d indicate the positions of the oligomers of phage λ cI1857 DNA run in the flanking tracks of these gels. The broken bars in d show the positions of the 23-kb fragment of a λ DNA/HindIII digest also run in the flanking tracks of this gel. The positions of these markers were determined by projecting the images of the ethidium bromide-stained gels onto the autoradiographs. e, Long-range map around island HTF 9. The map was constructed from the data shown in c and d and other similar experiments. In particular, there is a Nael site ~375 kb to the left of island HTF 9; this corresponds to a band towards the top of the NaeI track in the autoradiograph shown in a This band is beyond the markers on this particular gel and is not accurately sized at a short pulse time, therefore the size of this NaeI fragment was estimated from two other similar experiments in which the gel was run with a pulse time of 30 s. The error associated with fragment sizes is caused by the diffuseness of the hybridization signals. This uncertainty is indicated by the square brackets at the relevant restriction sites. The cluster of sites corresponding to HTF island 9 is underlined.

Methods. High-M, DNA was restricted with Nael, Narl, SacII or SmaI and analysed as described in Fig. 1 legend. The conditions of the pulsed-field gradient gel electrophoresis were chosen to optimize the resolution in the M_r range corresponding to the restriction site clusters. Filter transfer DNA from the pulsed-field gels was as follows: gels were incubated with gentle shaking in 0.25 M HCl for 40 min, rinsed in distilled water and incubated with gentle shaking in 0.5 M NaOH, 1.5 M NaCl for 60 min with one change. The gel was finally neutralized in 0.5 M Tris-HCl, 3 M NaCl pH 5.0 for 90 min with two changes. Transfer was done in $10\times$ SSC. Filters were hybridized to 20 ng of probe radiolabelled ¹³ to 2×10^9 c.p.m. μg^{-1} in a volume of 15 ml. GeneScreen Plus was hybridized according to conditions recommended by the manufacturer; nitrocellulose was hybridized in 5 × Denhardt's 5×SET, 0.1% SDS, 0.1% sodium pyrophosphate, 10% dextran sulphate at 65 °C. Filters were washed down to 0.2×SSC, 0.1% SDS, 0.1%

sodium pyrophosphate at 65 °C and autoradiographed for 2 weeks at -70 °C using an intensifying screen.

Table 1 Distribution of potential C-G endonuclease sites between bulk DNA and the HTF island fraction in mouse DNA

			m ⁵ C	No. of p sites per gen		Per cent sites	Sites per
Enzyme	Site	No. of CpGs	sensitivity*	Bulk DNA	Islands	in islands	island
Smal	CCCGGG	1	+	4.8	3.5	42	1.2
NaeI	GCCGGC	, 1	+	4.8	3.5	42	1.2
NarI	GGCGCC	1	+	4.8	3.5	42	1.2
SacII	CCGCGG	2	+	1.2	3.5	74	1.2

For the calculation of number of sites per haploid genome, we took the base composition of bulk DNA as 40% G+C, the CpG deficiency as 25% of the expected level, and the haploid genome size as 3×10^9 bp. HTF islands were assumed to comprise 1% of genomic DNA, to have a base composition of 65% G+C, and to show no deficiency of CpG.HTF islands of 500 to 2,000 bp have been found in mouse DNA, so for the purpose of calculation an average length of 1,000 bp has been assumed; this implies that there are 3×10^4 HTF islands per haploid genome and that they occur on average every 100 kb. The values for the number of sites in bulk DNA refer to the number of potential sites and do not take into account the effect of cytosine methylation which reduces the number of sites that can be cleaved by the enzyme.

* SmaI is a C·G enzyme which was known to be inhibited by methylation but nothing was known about the effects of methylation on the cleavage by other C·G enzymes. We tested NaeI, NarI and SacII by attempting to cleave the ribosomal DNA of Xenopus laevis either isolated in a molecular clone or in the sperm genome. Sequence data⁹ indicated that there are many sites for each of these enzymes within the untranscribed spacer of the ribosomal DNA and these could be cleaved in the molecular clone. The rDNA in sperm is 97% methylated at CpG (ref. 10) and was largely refractory to cleavage (not shown), thus we concluded that these enzymes are inhibited greatly by cytosine methylation.

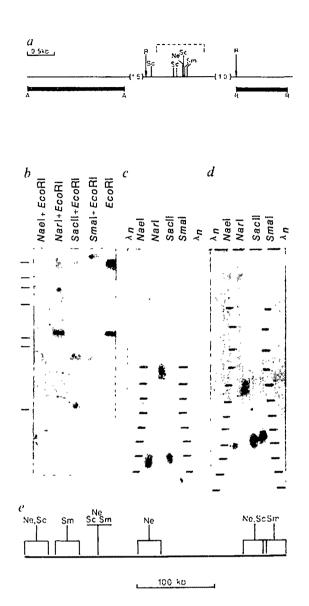

Fig. 3 Long-range mapping around island HTF 12. a, Restriction site map of island HTF 12. The probes used in the analysis shown in c and d are indicated by the bars beneath the map. The left-hand probe is an AccI fragment (abbreviated A). The right-hand probe is an EcoRI fragment. The broken lines indicate the extent of unmethylated genomic DNA. b, High-M, DNA either restricted with Nael, Narl, Sacll or Smal or incubated in restriction buffer without enzyme, was washed and EcoRI-restricted. Digests were analysed after conventional agarose gel electrophoresis using the central EcoRI fragment shown in a as a probe. Markers were the products of λ DNA restricted with HindIII. The sizes of the restriction fragments seen in the digests were estimated as (kb): EcoRI 2.45, Nael+ EcoRI 1.76, Narl+ EcoRI 2.53, SacII + EcoRI 1.7, Smal+ EcoRI 1.7. These values are consistent with Nael, SacII and Smal cleaving once within the island. c, Mapping to the left of island HTF 12. High-M_r DNA restricted with either Nael, Narl, Saell or Smal was fractionated by pulsed-field gradient gel electrophoresis and analysed by filter hybridization using the left-hand AccI fragment shown in a. Electrophoresis conditions: pulse time 30 s, run time 23 h, buffer temperature 15 °C, 300 V. d, Mapping to the right of island HTF 12. High-M_t DNA restricted and fractionated as above was analysed by filter hybridization to the right-hand EcoRI fragment. The electrophoresis conditions were as described for c. The bars on the autoradiographs show the positions of the oligomers of phage λ c1857 DNA run in the flanking tracks of these gels. e, Long-range map around island HTF 12. Construction details are given in Fig. 2 legend. The cluster of sites corresponding to island HTF 12 is underlined. Methods were as described in Fig. 2 legend except that all DNA samples were from within a single set of digestions and all filters were GeneScreen Plus

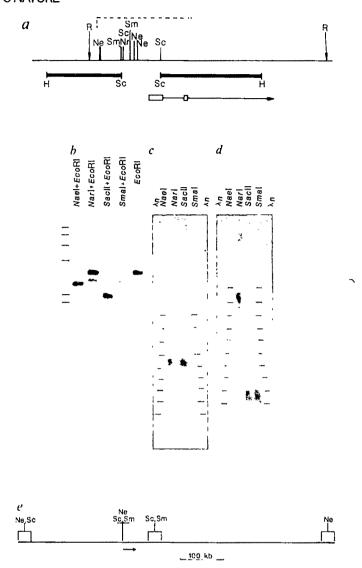

Fig. 4 Long-range mapping around the mouse dihydrofolate reductase gene (dhfr). a, Restriction site map of the HTF island at the 5' end of dhfr. The positions of the probes used in the analysis illustrated in b-d are indicated by the bars beneath the map. Also shown is the 5' end of the primary transcript. The first two exons are boxed. The broken lines above the map indicate the extent of unmethylated genomic DNA. H, HindIII. b, High-M. DNA either restricted with Nael, Narl, SaclI or Smal, or incubated in restriction buffer without enzyme, was washed and restricted with EcoRI. Digests were analysed after conventional agarose gel electrophoresis using the right-hand SacI-HindIII fragment shown in a as a probe. The products of phage λ DNA restricted with HindIII served as markers. The fragment sizes are as follows (kb): EcoRI 3.33, NaeI+ EcoRI 2.82, NarI+ EcoRI 3.33 and 2.93, SacII+ EcoRI 2.24, SmaI+ EcoRI 2.82. These values indicate that NaeI, SacII and SmaI all cleaved within this HTF island. The presence of an intact EcoRI fragment in the EcoRI + NarI double digest indicates that NarI did not cut completely in this island; this was also seen in a second experiment. c, Mapping to the left of dhfr. High-M, DNA restricted with either Nael, Narl, Sacll or Smal was fractionated by pulsed-field gradient gel electrophoresis and analysed by filter hybridization using the left-hand SacII-HindIII fragment described in a. Electrophoresis conditions: pulse time 30 s, run time 22 h, buffer temperature 16 °C, 320 V. d, Mapping to the right-hand side of dhf. High-M, DNA restricted and fractionated as above was analysed by filter hybridization using the right-hand SacII-HindIII fragment illustrated in a. Electrophoresis conditions: pulse time 30 s, run time 23 h, buffer temperature 15 °C, 300 V. The bars on the autoradiographs show the positions of the oligomers of phage λ c1857 DNA run in the flanking tracks of these gels. e, Long-range map around dhfr. The map was constructed on the basis of the data shown in c and d. The left-hand SmaI site was not mapped because a possible hybridizing fragment was obscured by a scratch on the autoradiograph shown in d. In a second experiment the Smal digest was only partially complete at the dhfr HTF island. The position of the 34-kb dhfr primary transcript is indicated by the arrow. The cluster of sites corresponding to the dhfr HTF island is underlined. DNA samples were all from within a single set of digests and all filters were GeneScreen Plus. For other details see Fig. 2 legend.

In the present study we have used pulsed-field gradient gel electrophoresis to map cleavable sites for the enzymes Nael, NarI, SacII and SmaI over ~1.5 million base pairs of the mouse genome. As predicted, the sites available for cleavage by these enzymes (in other words, non-methylated sites) occur in clusters which correspond to regions rich in non-methylated CpG. Additional recognition sites for the enzymes are present outside clusters but most of the potential sites in these regions are probably not cleaved because they are methylated. Making the assumption that sites of cleavage by more than one enzyme represent HTF islands, the average distance between islands in the mapped region is 109 kb (mean of seven values). The average distance between islands has been indirectly estimated as 100 kb (ref. 3), which agrees quite well with the present value. It is clear, though, that variation about the mean is considerable.

CpG-rich islands have now been found in association with many genes (reviewed in ref. 8), and it is likely that a high proportion of the 30,000 or so HTF islands are gene-associated. As many genes with HTF islands are already available as molecular clones, it will be possible to use the strategy of mapping from HTF islands to tackle a variety of longrange mapping problems. Moreover, the putative HTF islands identified by the map data may lead directly to new genes.

We thank Chris Tyler-Smith and Howard Cooke for comments on the manuscript, Patrizia Lavia and Donald Macleod for access to unpublished data, Jean Scott for a cosmid containing the 5' end of dhfr and Anne Deane for typing the manuscript.

Vitreoscilla, a filamentous bacterium in the Beggiatoa family, synthesizes a soluble haemprotein which has two identical subunits of relative molecular mass 15,775 and two b haems per molecule¹. It is synthesized in relatively large quantities when the organism, a strict aerobe, is grown under hypoxic conditions². It forms a relatively stable oxygenated form which is spectrally similar to oxymyoglobin (oxyHb) and oxyhaemoglobin (oxyHb)3. The amino acid sequence of this protein has been determined and aligned to fit the helical regions of several animal and plant globins. This alignment is consistent with its being a structural homologue of the eucaryotic haemoglobins although it diverged from the others in the N-terminal region and may lack an A-helix. It showed the maximum sequence homology (24%) with lupin leghaemoblobin (Lb). Vitreoscilla Hb is the first bacterial haemoglobin to be sequenced. It may function to enable the organism to survive in oxygen-limited environments by acting as an oxygen storage-trap or to facilitate oxygen diffusion.

Partially purified preparations of this Vitreoscilla haemprotein, which was previously called soluble cytochrome o, contained NADH-cytochrome o reductase activity, exhibited slow turnover of the NADH, oxygen consumption, and it was presumed that this protein functioned as a soluble terminal oxidase³. An oxygenated form detectable in these preparations was subsequently observed to be the predominant species of the protein present in intact cells of the bacterium during aerobic respiration⁴. The latter result and more recent experiments have provided evidence against the function of this protein as an oxidase. A true membrane cytochrome o was identified by photolysis of CO-liganded intact cells at −100 °C and eventually purified, and a cytochrome d was also identified. The need for a soluble oxidase in the presence of these established membrane terminal oxidase became even less evident. When the CO-compound of the protein was photodissociated with a dve laser in the presence of oxygen, or when the oxygenated compound itself was photodissociated, recombination with oxygen occurred with no evidence of oxidation of the heme iron? is in contrast to results expected for a terminal oxidase and observed for cytochrome c oxidase but similar to what is observed for oxygen binding proteins like haemoglobin and myoglobin9. An infrared spectroscopic study of the stretch band for oxygen liganded to the heme iron showed that the absorption band was similar to those observed for oxymyoglobins and oxyhaemoglobins, evidence for a similar bent-end-on oxygenyltype bonding¹⁰. Finally, the results reported here show that the amino acid sequence has considerable homology with that of yellow lupin Lb II. Consequently, we have reconsidered the role of this protein as a terminal oxidase and now propose that it is a haemoglobin-like protein which will accordingly be called Vitreoscilla Hb hereafter.

A summary of the sequence analysis of Vitreosculla Hb is shown in Fig. 1. It consists of 146 amino-acid residues with a calculated relative molecular mass of 15,775 for the aposubunit, somewhat larger than the 13,000 estimated previously by SDS polyacrylamide gel electrophoresis¹. The sequence of the carboxymethylated protein was determined using trypsin and Staphylococcus V8 protease digestion, separation of peptides by HPLC on an ODS column, and manual and automated solidphase Edman degradations^{11,12}. The only technical difficulty that was encountered was in deducing the sequence near the C-terminus of the polypeptide chain.

Carboxypeptidase Y released alanine, leucine, valine, glutamate, and several other amino acids from the carboxymethylated protein, but no peptide with these amino acids as C-terminus was isolated. The C-terminal tryptic peptide, T-11, which could not be recovered from the HPLC column, was obtained by precipitating the digest with dilute acetic acid and although impure was successfully sequenced, but the C-terminal amino acid could not be determined because again carboxypeptidase Y digestion released many amino acids. Chymotryptic digestion of peptide T-11 gave three peptides, and their amino-acid compositions were in agreement with the sequence of T-11. Curboxypeptidase Y digestion of peptide C-3 released a small amount of glutamic acid. Since glutamic acid does not fit the cleavage site specificity of either trypsin or chymotrypsin we assigned peptide C-3 to be the C-terminal peptide of the cytochrome. Although Vitreoscilla Hb is the first bacterial haemoglobin to be sequenced, a soluble Rhizobium haemoglobin has been reported in free-living (cultured) cells of Rhizobium that is unrelated to Lb and has about the same molecular size as Vitreoscilla Hb13

The sequence of Vitreoscilla Hb is aligned for comparison with other haemobins in Table 1. It shows the greatest sequence homology with lupin Lb14. The final alignment shown was obtained from the initial computer alignment by positioning hydrophobic residues at the approximately thirty sites where internal hydrophobic residues are conserved in the normal globin structure¹⁵. This was accomplished with several

R is an arbitrary residue number with the numbering beginning from the N-terminal of the globins with the longest N-terminal extension. H refers to the helix position in sperm whale myoglobin. The haemoglobins are: HHB α , human α -chain; HHb β , human β -chain; SWMb, sperm whale myoglobin; GHb, Glycera haemoglobin; LLb, lupin leghaemoglobin; VHb, Vitreoscilla haemoglobin. Sequence data for the first five proteins were taken directly from ref. 14, omitting three residues which were each inadvertently entered twice in the sequence for LLb presented there.

* Residues in Vitreoscilla Hb that match those in lupin Lb.
† Conserved, buried hydrophobic residues²³.

Fig. 1 Sequence analysis of Vitreoscilla Hb. T-, V- and C- refer to tryptic, Staphylococcus V8 protease and chymotryptic peptides, respectively. Arrows above the residues at N-terminal regions indicate the results of N-terminal sequence analysis of the apoprotein. Arrows (\rightarrow) , (\rightarrow) and (\leftarrow) show automated solid-phase (DITC method) Edman degradation, manual Edman degradation, and carboxypeptidase Y digestion, respectively. Dotted arrows indicate ambiguous identifications (---) or unrecovered residues by the solid-phase method (\rightarrow) .

exceptions which are probably not important (Glu at G11 and Ser at E4). The final alignment has His at F8, the proximal ligand, and the invariant Phe at CD1. The usual residue at E7, His, the distal ligand, is replaced by Gln, which has been observed in the α -chain of opossum Hb and would also be capable of forming a hydrogen bond with the bound oxygen. There are 35 matches with the 153 residues of the lupin legHb. a 24% identity per length. The number of identical residues among these various globins is given in Table 2. Note that the number of identical residues between sperm whale Mb and

Table 2 Identical residues matrix: the number of matching amino acid residues among the sequences of the globins in Table 1

human Hb chains is approximately the same as that between Vitreoscilla Hb and Lb, which is indicative of significant homology. In addition to the identical matches there are 20 similar residue matches, such as Glu/Asp, Ser/Thr, Leu/Val/Ile, Phe/Tyr, and roughly another twenty 'neutral' matches. The N-terminal region of the Vitreoscilla Hb does diverge from the other globins listed in Table 1, and the A-helix appears to be incomplete or lacking.

It is premature to speculate whether Vitreoscilla Hb shares a common evolutionary ancestor with the plant and animal haemoglobins or is the product of convergent evolution. We found no notable sequence homology between Vitreoscilla Hb and various cytochromes by computer analysis. Some observed similarities in the primary sequences of various globins and b-type cytochromes led Runnegar to propose that all globins are monophyletic, the common ancestor being a b-type cytochrome¹⁶. The existence of bacterial haemoglobins implies that this common ancestor would have to be a bacterial b-type cytochrome.

The following observations relate to the function of Hb in Vitreoscilla. The cellular haem content is dependent on the dissolved oxygen in the growth medium and increases about 50-fold when the oxygen concentration falls below about 10% atmospheric²; most or all of this is due to an increase in the Vitreoscilla Hb17. Species in this genus tend to live in oxygenpoor environments such as stagnant ponds and decaying veget-

able matter18, they are unable to ferment sugars, and their metabolism appears limited to aerobic oxidation of amino acids¹⁹. An adaptation to hypoxic conditions by increasing the concentration of terminal oxidases in the cellular membrane is unlikely because enzymatically active membranes, which include chloroplast, inner mitochondrial, and bacterial cell membranes, already have a protein to lipid ratio of around 3:1. in contrast to a ratio of roughly 1:1 for most animal cell membranes²⁰. An increase in membrane terminal oxidase would likely result in destabilization of the membrane. On the other hand, the concentration of haemoglobin in erythrocyte cytoplasm is more than 80% that of the crystalline protein²¹. Thus, the concentration of Hb could increase to very high concentrations in Vitreoscilla cytoplasm, without adversely affecting its normal metabolism, where it could then function as an oxygen storagetrap to enable the organism to survive in oxygen poor environments. Alternatively, if it were localized near the bacterial plasma membrane it could function to facilitate oxygen diffusion to the membrane terminal oxidases²². Perhaps primitive haemoglobin first appeared to play a similar role during the evolution of aerobic respiration.

The authors are indebted to Drs Russell, F. Doolittle and Peter E. Wright for invaluable assistance with the sequence homologies. Most of this work was done while D.A.W. was on a sabbatical leave in Japan supported by US NSF grant INT-8212086. Partial support also came from the US PHS NIH grant GM27085.

Homology between IgE-binding factor and retrovirus genes

THE recent report by Toh et al.1 of sequence homology between segments of a cloned gene encoding rodent IgE-binding factor (IgE-BF)² and a gene encoding Syrian hamster intracisternal Aparticle (IAP)³ is an intriguing observation. However, we must express reservations about Toh et al.'s interpretations of the observed homology.

First, the authors claim that because the N-terminal third of the IgE-BF coding sequence shows no homology with their particular IAP gene, the IgE-BF gene must be "a hybrid gene which evolved...by integrating genes of viral origin". No evidence is presented by either Toh et al. or Martens et al.2 in support of the authors' assertions that the cloned IgE-BF gene is a hybrid gene or that it even contains a portion of a non-IAP gene at all. Neither report presents any genomic blot data to indicate whether homologous genes exist in the mouse or rat genomes. Here, the conclusions of Toh et al. are considerably weakened by the fact that their sequence comparison crosses species lines; they really have no justification for making any statement regarding the nature of IgE-BF sequences which do not show homology to their hamster IAP sequence. Thus, their assertion that the N-terminal third of the IgE-BF amino-acid sequence is unique to IgE-BF is speculative and not supported by their data.

The IgE-BF clone was derived by Martens et al. from a rat-mouse T-cell hybridoma. Toh et al. do not mention the possibility that the IgE-BF clone could represent a hybridoma-related recombination event, as opposed to an evolutionarily significant insertion of a retroviral-related sequence into "a cellular DNA region proximal (sic) to a primordial IgE-BF gene". Observations suggesting such an alternative explanation exist in the literature⁴⁻⁶. These data all demonstrate that in the mouse genome, IAP genes are mobile elements which can affect the expression of unrelated genes. Toh et al. overlooked the possibility that the structure of the cloned IgE-BF gene could have arisen by insertion (in the hybridoma) of an IAP sequence distal to the IgE-BF coding sequence, followed by transcription of this region and splicing of the "'IgE-BF', gag and pol" sequences. In view of this possibility, it is important to stress that the IgE-BF clone is a complementary DNA, rather than a genomic clone; Toh et al. make inferences of considerable import about the structure and evolution of a putative genomic gene from sequence comparisons involving only a cDNA clone.

Taken together, the arguments outlined above also cast doubt on the statement of

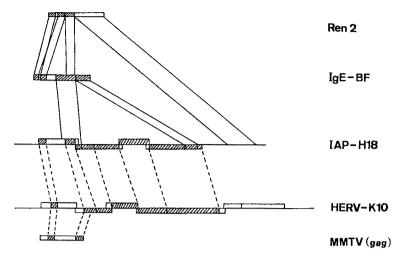

Fig. 1 Profiles of sequence homology of IgE-BF cDNA to mouse (Ren 2) and hamster (H-18) IAPs, human endogenous retrovirus (HERV-K10) and MMTV gag. Homologous regions are indicated by slanted lines. Regions where homologies exist at the DNA level and at the protein level are connected by vertical straight lines and dotted lines, respectively.

Toh et al. that a particular proteolytic cleavage of the precursor IgE-BF is more likely than another to generate the 11K (relative molecular mass 11,000) IgE-BF from the 60K species.

Thus, we believe that while the observations of Toh et al. are of interest, conclusions about their possible significance are speculative, and certainly premature in the absence of any experimental data examining the relationship of IgE-BF to IAP. A preliminary report of the homology of IgE-BF to mouse IAP genes appeared earlier, but was not cited by Toh et al.

MIYATA ET AL. REPLY-We have shown previously1 that the IgE-BF cDNA from a rat-mouse T-cell hybridoma² exhibits a strong sequence homology to the Syrian hamster IAP3 at the nucleotide level in the 3' two-thirds of the protein-coding region, whereas the remaining 5' one-third shows obvious homology. This

homologous region of the IgE-BF cDNA, however, shows sequence homology to a mouse IAP (Ren 2)4 at the DNA level, but not to a distantly related human endogenous retrovirus, HERV-K10 (M.O. et al., in preparation) or to a mouse mammary tumour virus (MMTV)⁵ gag region, both of which share obvious homology with the hamster IAP at the protein level (Fig. 1). Moore et al.6 recently demonstrated sequence homology of the IgE-BF cDNA to mouse IAPs, represented by MIA14, over its entire regions. These results suggest that the nucleotide sequence corresponding to the 5' third of the IgE-BF coding region is unique to mouse IAPs or their close relatives. This unique region might have been derived very recently from a distantly related retrovirus or an endogenous retrovirus by a recombination mechanism, or from a primordial IgE-BF gene of cellular origin, as suggested previously1.

EARLY HOMINID PHYLOGENY

IVIASSION The new force in bi

ZetaPrep® Technology. Engineered for mass ion exchange. Powered with a unique solid matrix. Thrusting you in to a new age of upstream purification. Boosting mass flow and volume flow with results that outdate every other known separation method. Giving you quantum savings in time and money.

Unique solid matrix!

Designed for highly efficient, ultrafast extraction of proteins, peptides and enzymes, the ZetaPrep solid matrix comes in a cartridge that's completely self-contained. With its unique, multi-directional radial flow, this patented rigid format offers optimal surface area for rapid bulk binding, plus the strength to withstand high flow rates.

All ZetaPrep housings and cartridges are completely sterilizable and compatible with standard equipment. Shown here is the ZetaPrep 100 for laboratory separations.

Economics you just can't ignore!

Capable of one-step puri-

fication and concentration with up to 80% purity or more, ZetaPrep will slash your production costs to a fraction of what they are today. Because ZetaPrep is so easy to operate, simple to automate and efficient in use, you'll cut expensive man hours to a minimum.

ZetaPrep's incredible flow lets you radically reduce total processing time. Gets you fast binding, wash and elution flow rates. And at least 10 times higher throughput. With no more packing problems. No more fines removal. Just all the benefits of a totally enclosed system—and yields that are truly astounding.

Amazing scale-up potential

LKB's comprehensive range of ZetaPrep cartridges and Multi-Cartridge Systems lets you select different sizes, extend in series or even couple in parallel for virtually unlimited flow rate and process capacity. With DEAE, QAE and SP functional groups, you can now exploit this amazing scale-up potential from lab, through pilot to fullscale industrial production. In biotechnology, pharmaceuticals or any other process that needs cost-effective purification of proteins and biopolymer products.

EARLY HOMINID PHYLOGENY

The find of a new 'robust' hominid west of Lake Turkana. Kenya in sediments much older than previously associated with these forms throws into doubt the relationship with other species of Australopithecus, and more widely, the pattern of human phylogeny. From analysis of several features and comparison with a specimen from the Olduvai Gorge in Tanzania, the new find is considered to be A. boisei. See p.517. The implications of this find are discussed further on p.496...

A new era in cell culture has arrived. Invitron's Static Maintenance Reactor (U.S. Patent No. 4,537,860) is the result of a 15 year marriage of cell biology with bioengineering. This revolutionary cell culture bioreactor approaches—within a pharmaceutical environment—the condition under which cells exist in living tissue.

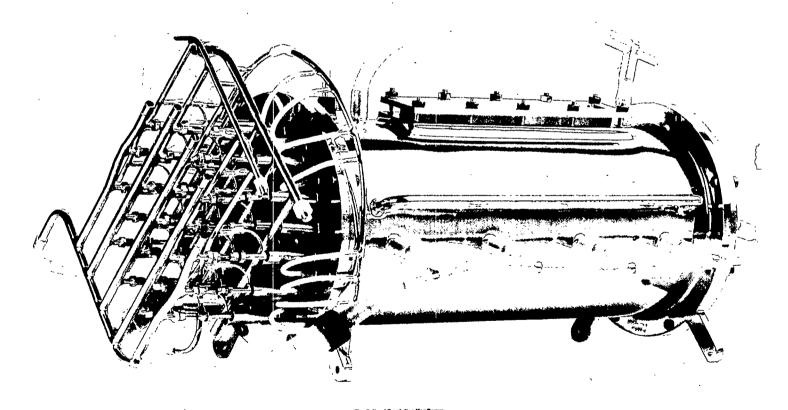

Just one of these reactors has the capacity to produce multi-gram quantities of product...everyday...for months at a time. Annualized, this means that each reactor has multi-kilogram capacity.

GUIDE TO AUTHORS

Authors should be aware of the diversity of Nature's readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (hgures plus tables). The article should include an italic heading of about 50 words.

Letters to Nature are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in Nature. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted

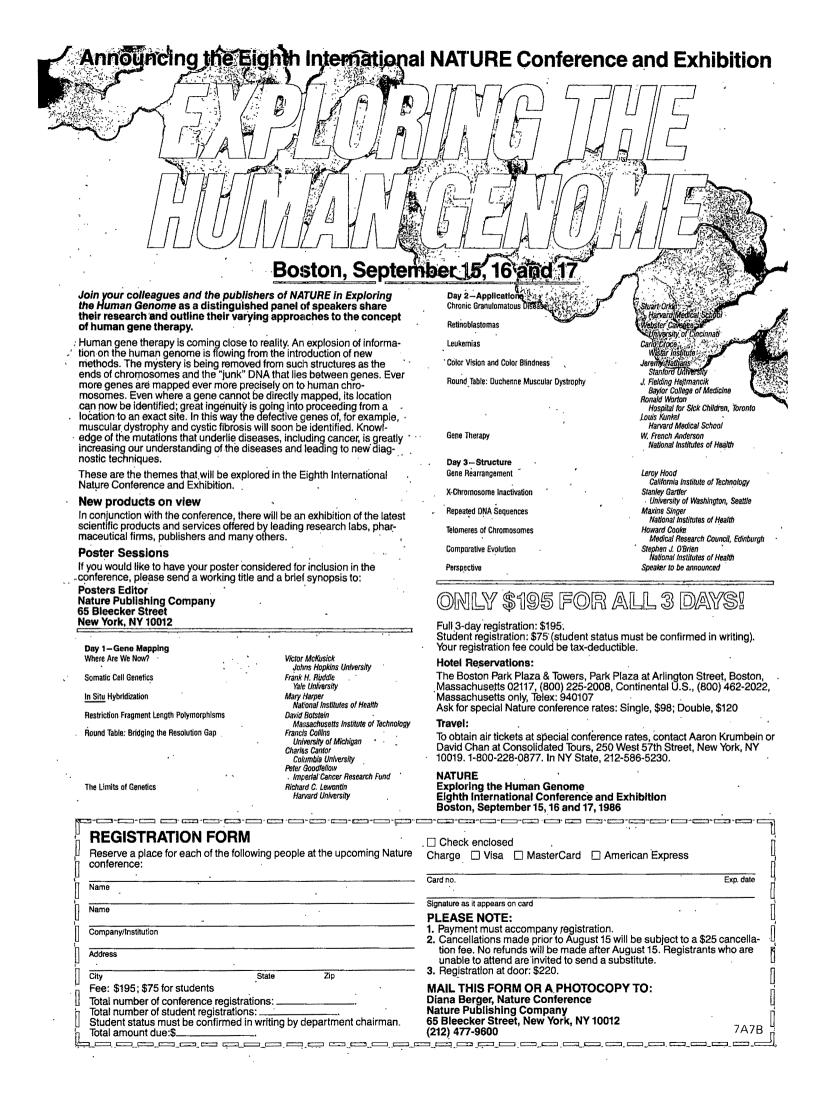

Manuscripts may be submitted either to London or Washington. Manuscripts should be typed (double spacing) on one side of the paper only. Four copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc, should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts, in the text and should be abbreviated according to the World List of Scientific Periodicals, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be cited. Reference to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for coverillustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Important: Manuscripts or proofs sent by air courier should be declared as "manuscripts" and "value \$5" to prevent the imposition of Customs duty and Value Added Tax in the United Kingdom.

Requests for permission to reproduce material from Nature should be accompanied by a self-addressed tand, in the case of the United Kingdom and United States, stamped) envelope.

NATURE VOL. 322 7 AUGUST 1986 . 485

Rigging the price of silicon chips

The agreement signed last week between Japan and the United States will not in the long run keep Silicon Valley healthy, and meanwhile will be a recipe for trouble.

ONLY a few days after one of the largest steel-makers in the United States, the conglomerate LTV, ran for the shelter of the US bankruptcy laws, trade officials in Washington were foolishly celebrating last week the agreement they have negotiated with their opposite numbers in Japan to regulate the sale of semiconductor memory chips between their manufacturers. The coincidence is striking and also chilling. LTV has been driven into queer street by the long decline in the demand for steel when the world is swimming with the capacity to produce . the stuff. During much of that time, the US government has done what it can to protect the domestic industry from overseas competition by a variety of restrictions on the free import of steel. Voluntary quotas have been negotiated with European steel-makers, while the policy of protection has been stiffened by the usual array of anti-dumping suits in the courts. The result is that the US steel industry has been kept alive, but only just.

Technically, the industry has limped along, maintaining existing plants without the funds to improve them to a point at which they might compete effectively with steel-makers in Japan and Korea. The companies involved have in the process been locked into a declining business when their long-term interests would have dictated diversification. What has happened to the US steel industry is yet another proof that, in a competitive world, protection is more often the kiss of death than a safeguard. How soon will this truth be demonstrated in the manufacture of silicon chips?

The new agreement is believed to cover something like 90 per cent of the semiconductor manufactures supplied by Japan to the United States. All the bread and butter in the trade will be regulated, but, almost by definition, the regulations will not apply to the most advanced components, those so novel that competition has not yet developed and whose lucky manufacturers can charge what prices they choose, not to mention the chips not yet invented. The agreement binds both signatories to ensure that chips are not sold for export at prices other than those defined as fair, which implies that manufacturers will have to recover in their prices not merely the marginal cost of production but also a contribution towards the capital costs of the plants in which chips are made.

Technically, the agreement is a recipe for endless bickering. Difficulties have arisen about the prices charged for chips because of the huge difference, in a capital-intensive business, between the marginal cost of production and that which fully amortizes the cost of the equipment with which chips are made. Who will now decide what production overheads are fair? But in practice, the effect of the agreement promises to be unambiguous: prices of chips of all kinds will be increased for everybody, often substantially.

For a time, no doubt, there will be rejoicing in Silicon Valley, the Californian hub of the US computer industry. Small companies whose backs have been against the wall for months on end will be able to walk tall again, sheltered from the formidable competition of Japanese manufacturers by increased prices. The new deal may not restore the full excitement of the 1970s, when for a time it seemed as if Californian entrepreneurs had stumbled on the modern equivalent of the philosophers'

stone, a way of turning silicon into gold. But there will be fewer lawyers preoccupied with the intricacies of Chapter XI, the provisions of the bankruptcy laws that allow a company to keep trading while protected from the most pressing claims of its creditors. Undoubtedly there will be a spell, of months and possibly years, during which the sales of the US chip-makers will increase, both in volume and in profitability.

Japanese manufacturers will be compelled to compete in other ways, two of which are easily foreseen. First, they will pay even more attention than is their present custom to the quality of what they manufacture and put on the market. Second, compelled by the agreement to charge more for what they sell at present and thus made even more profitable than they are now, they will invest even more enthusiastically in novel semiconductor devices. A few years from now. Silicon Valley will probably still be a high-cost producer, but may well have lost its present reputation for daring design behind the shield for foreign competition now being provided. That is what has happened to steel manufacture in the United States

Meanwhile, the economic cost of the new agreement will be felt throughout the world. To prevent manufacturers in Japan selling cheaply into the United States through the intermediary of third countries, price-fixing will apply to chips sold by both Japanese and US companies in, for example, Europe. One result will be that the prices of electronic equipment will be increased. Another will be that European chip-makers will enjoy the benefits being showered on Silicon Valley at a crucial time in their strategic history, when the case for making chips indigenously is stronger than it has ever been. Whether European companies will ever be able to match those in Japan in quality and cost is an open question, but now at least they will have an opportunity to do so. Is that what the United States intends?

That the new agreement will not serve its intended purpose, but others that cannot accurately be foreseen, is beyond dispute. Yet one malign side-effect is easily predicted. To the extent that the new agreement on chips establishes an inter-governmental cartel for the regulation of prices in international markets, it will be an awkward precedent that is bound to come to haunt the United States, hitherto an admirably staunch supporter of the doctrine that free trade is the only effective means of arriving at an economic division of labour in the world. Which other governments, in respect of other manufacturers, will now be tempted to follow suit? All they will have to dissuade them is the example of the Organization of Petroleum Exporting Countries (OPEC), now in collapse along with the price of crude oil.

Selling the family silver

Turning public into private enterprise is fashionable, but not best done by public servants.

LORD Stockton, previously Mr Harold Macmillan, last year startled the British government which he supports politically by reproving it for "selling the family silver" in order better to balance its accounts. The circumstances are now familiar, and by

no means exclusively British, even if the present British government is among the most zealous of those attempting to turn public into private enterprises. (M. Chirac's government in Paris seems anxious to follow suit, if President Mitterrand's reluctance is in the end overridden by the French Assembly.) Already a majority of the shares in the previously nationalized telecommunications network and the aerospace company have been sold to the public. The gas monopoly is to be sold later in the year, but there will be a long delay before the complicated water industry can be made private, and it remains to be seen whether the government can find a buyer for the motor-car manufacturer it owns who will be acceptable to its own supporters (who, with others, killed the attempt to sell part of it to US General Motors a few months ago).

Meanwhile (see, p.491), at the other end of the spectrum financially, the government has managed to work out a way of selling off its interest in the breeding of commercial crops through the Plant Breeding Institute at Cambridge (England). In principle, this is a sensible step to take. Like all the other research institutes operated by the Agricultural and Food Research Council (AFRC), the Plant Breeding Institute has had a rough and over-spartan time in the past few years. Budgets have been held stagnant or even cut, with the result that vacant posts have not been filled even when there is productive work for their potential occupants to do. But the institute differs from most others in that the benefits of the work it does are translated directly and tangibly into monetary terms. The new varieties developed at the institute are sold to farmers, in Britain and overseas, through bodies such as the National Seed Development Organization, which regularly makes a substantial profit on its operation that, under the present system, has been dutifully turned over to the British Treasury. Taken together and averaged over the years, the profits of the seed organizations are not very different from the costs of the research that has sustained them, which vividly illustrates the folly of having kept the institute on such short commons all these years. Now the breeding and marketing organizations are to be put up for sale as a package. There is a chance that the new entity will be able to make its way in the world relatively free from worry, and even more conscious of how its skills (widely acknowledged to be high) should be most effectively deployed.

That is the plus side of the account. The other is the decision that, in the process of privatization, the Plant Breeding Institute should be split in two. Plant breeding pure and simple (if there is such a thing these days) is part of the commercial package, but molecular biology will stay in the public sector. That, at least, is the intention, however little sense it makes when plant breeders the world over are bent on using genetic manipulation to give crop varieties characteristics they would not acquire naturally. If the institute is indeed sold off successfully (as seems likely), the new owners would promptly set out to recruit a team of molecular biologists to make up for the loss now being decreed. They would not have far to look.

None of this implies that research councils such as AFRC should withdraw from the molecular biology of plants. On the contrary, there is the strongest possible reason why the scale of effort in this field should be increased even in circumstances such as those in Britain, where farming is no longer strictly an economic activity (see Nature 322, 195; 1986). But the opportunity for spinning off a substantial team of people working in the field already should be regarded as a heaven-sent chance for creating another. This is a chance to sell the family silver and to get another set. Luckily, it is not too late for the government and AFRC to change their minds. Indeed, on the principle that the British government in its present mood is unlikely to increase the funds available for supporting basic research but, equally, is unlikely to have the gall to cut them even further, there is a strong case for scouring government departments for other parts of the public research enterprise that might be thrown to the commercial wolves.

Taxes make big waves

The effects of US tax reform will be felt far outside the United States.

BEFORE the summer is out, the US Congress will have put the finishing touches to the tax bill that is almost certain to be what the Reagan administration is remembered for. That, at least, is the plan, which is likely to be sustained by the way in which general enthusiasm for lower percentage rates of tax promises to. overcome taxpayers' attachment to the labyrinthine network of deductions from income they have long regarded as their birthright. While the marginal rates of tax are still to be determined, the mere idea that there may be just two, at 15 per cent and 27 per cent, will excite the envy of taxpayers elsewhere, many of whom are used to surrendering more than half of the extra they earn. Even if the rates at which optimistic congressmen are aiming cannot be achieved, or if it turns out that the extra taxes that business will have to pay are economically damaging and must be reduced, the simplicity of the new tax bill cannot fail to be seductive elsewhere.

There will be more immediate and specific consequences, one of which may benefit the economic partners of the United States. The details of the new bill are still being negotiated between the US Senate and the House of Representatives, and there is much to be worked out. The Senate version of the bill is generally considered friendlier to business, perhaps reflecting its Republican majority. By contrast, the House version generally provides greater savings to individual taxpayers. Arriving at a compromise that will be acceptable to at least a majority of legislators is proving to be at least as hard as analysts predicted it would be. But one feature likely to emerge intact is the proposed abolition of the tax shelter embodied in the device of the limited partnership; its effect will be to send venture capital scurrying to other places in the industrial world where investment in innovation is still encouraged by such means. The principle is that people may invest part of their income in some new venture, which may be a new company or even just a new project on which a company is engaged, pay no tax on that slice of income but pay capital gains tax on their profits if the venture should succeed. The device has been widely used in the past few years in, for example, the development of biotechnology. If, now, such opportunities are no longer available in the United States, individuals and corporations with income arising elsewhere will be tempted to look for them where they can. Already there are people in Europe calculating that the flow of venture capital across the Atlantic may be substantial.

The other side of that coin is that the dazzling attractions of the tax reform bill may, over a longer period of time, work in the other direction. Ever since the Second World War, the United States has been a magnet for technical people elsewhere. The canard that engineers in the United States are so busy at their profession that they have no time for teaching, with the result that the education of young engineers is in the hands of people from overseas, is at least a half-truth. Other governments are often alarmed enough to mount formal inquiries into what they call the brain drain, only to discover that their emigrating technical people proclaim that they are leaving for the United States only because working facilities are better there, or that they seek the chance of working alongside particular colleagues. But this is humbug, and should be recognized as such. Is there any reason to believe that technical people are immune from the prosperity that makes the United States attractive not merely to other professionals but to the army of unskilled people who seek the same haven? By that test, the rate at which technical people depart for the United States will only be accelerated when the tax bill passes. Are governments elsewhere reconciled to that alarming prospect? And will they choose to follow the only course by which they might convincingly respond, that of mimicking what is now happening in Washington?

US budget

Winners and losers worry about Gramm–Rudman

Washington

CLEAR signs emerged last week that the US Congress may be unwilling to support some of the increases in research funds proposed in President Reagan's budget for the next financial year, beginning in October. Faced with strong political pressure to reduce the federal budget deficit, the Appropriations Committee of the House of Representatives recommended providing the National Science Foundation (NSF) with \$136 million less than the \$1,686 million sought by the President, giving only a slight real increase over this year's level. A small cut of \$44 million from the President's request was also proposed for the National Aeronautics and Space Administration (NASA).

The still uncertain effect of last year's Gramm-Rudman deficit control act makes prediction of agencies' budgets difficult. But academic and scientific bodies did not hide their dismay last week that Congress had failed to support the 8 per cent increase sought by the President for NSF, the main federal source of support for non-military basic research. Jack Crowley of the Association of American Universities was disappointed that a key committee of Congress saw increased support for basic research as "an expendable priority". Others pointed out, however, that the committee had in the same legislation approved significant reductions for other agencies and that it had gone as far as it could to protect NSF.

The National Institutes of Health (NIH) are, however, another story. The House of Representatives excelled even its own customary generosity to NIH by voting to provide \$6,153 millon for the institutes, \$1,073 million more than the President's budget request and \$893 million more than the 1986 figure. The House specifically noted that it wanted to see 6,200 new extramural research grants next fiscal year, about 700 more than the administration wanted. While the Senate might temper the House's enthusiasm, there seems little doubt that Congress's strong support for NIH is unchanged from previous years.

During the House debate that preceded the vote, much was made of the growing death toll due to AIDS (acquired immune deficiency syndrome), and \$336 million was voted for efforts to combat the disease, \$133 million more than the President had requested.

Other appropriations bills on which the House has taken action include a bill providing funds for the Department of Energy. Here the House has also followed the pattern of previous years by voting to restore some of the large cuts proposed by the President in solar power and magnetic fusion research. But at the same time it cut \$536 million from the \$8,330 million budget request for the department's defence programmes, to take account of limits placed by Congress on growth of the Strategic Defense Initiative.

The House has, however, alarmed academic groups by allowing to pass in the same bill \$69.7 million for research and construction projects at eight named institutions that have not been through the usual process of authorization by Congress and have not been subject to peer review. Most scientific and academic bodies are opposed to Congress's growing tendency to provide funds for specific unreviewed construction projects from research budgets. But Congress seems in no mood to compromise. An amendment to delete funds for the unreviewed projects was defeated by 315 to 106. The Senate has yet to consider the matter, but recently defeated a move to delete funds in a Department of Defense emergency money bill for unreviewed projects at nine universities (see Nature 322, 4: 1986).

Most of the appropriations now at various stages of approval in the House have not reached the Senate. But the exact amounts specified by both houses could become largely irrelevant if, as some expect, a legislative formula is found to allow automatic cuts to be made to agencies' budgets to make them comply with the \$144,000 million budget deficit target specified by Gramm-Rudman.

Although the mechanism specified in Gramm-Rudman for making the automatic cuts was ruled unconstitional by the Supreme Court in July, efforts are under way to modify it. The court's objection was over the pivotal role played by the General Accounting Office in determining the size of the cuts; one proposal now under consideration would meet that difficulty by substituting the executive branch's Office of Management and Budget.

A preliminary estimate of the likely budget deficit next year will be made on 15 August and, if the target is exceeded by more than \$10,000 million, the necessary across-the-board cuts would then be calculated. If Congress has not by then completed appropriations for the next fiscal year, the 1986 levels will be used in the calculation, a prospect particularly alarming for agencies such as NSF that had been

in line for large increases. I ven it the automatic cuts are not made, however, there will be strong pressure on Congress to meet the targets in the Gramm-Rudman law.

Many congressional staff now consider it inevitable that the cuts will be triggered: slow economic growth has reduced expected revenues and a deficit of around \$220,000 million seems likely, it Congress sticks to the budget guidelines agreed earlier. The cuts would probably be much bigger than the 4.3 per cent made this year. But congressional elections in November could prove to be the wild eard Some observers think that Congress will yet devise some way of getting itself off the Gramm–Rudman hook before November.

Inventors' rewards

THIRTY-three British universities and colleges have gained permission to exploit financially inventions arising from research funded by the research councils. Until now the British Technology Group (BTG) has had right of first refusal for the commercial development of government-funded research, a process that its just released annual report shows is not without its dangers.

Last year, BTG, a state-owned management company formed to assist the commercialization of innovative ideas, had to spend more than a million pounds defending its patent rights. Most of the money went on fighting for the hovercraft — a great British invention back in 1959 now being put into use by the US Armed Forces. The trouble is they are not paying the royalties and "American lawyers are very expensive" as a BTG spokesperson put it. But BTG still managed an income of nearly £20 million from licensing and industrial projects.

Before being granted permission to try for similar profits on their own, the universities had to assure a scrutiny committee that they knew what they were about. The chief aim, in line with government policy. is to provide new incentives for individual researchers as well as their universities. That aim can be satisfied only by arrangements in which inventions with a potential for commercial exploitation can be spotted early; flexible routes for their exploitation, including setting up new companies and forming partnerships with industry, can be quickly set up; and inventors properly rewarded. That may mean the inventor will get all the proceeds if the invention has a low level of return, and the university gets a cut when bigger profits can be made.

Universities that have not yet received permission to exploit their inventions are likely to do so in the near future. Some, though, will continue to use existing arrangements with BTG. Alun Anderson

European nuclear power

Muddle over safety measures

A swingering attack on the European Economic Community (EEC)'s nuclear safety and public information record was delivered in Brussels last week by its commissioner for the environment, Stanley Clinton Davies. His remarks were apparently based on a new report from an expert committee — but those involved in the report's preparation claim it reaches wholly opposite conclusions.

The report, due to be published in a few months, was drawn up by those close to the nuclear industry and it supports its policies, according to Commission sources. It is regarded, however, only as advice and the European Commission is free to draw its own, even contradictory, conclusions.

Clinton Davies's interpretation was certainly affected by the uncoordinated response by European states to the Chernobyl nuclear disaster, which came late in the expert group's year-long deliberations. In that context, the commissioner felt it necessary to criticize the poor and late provision of public information in some countries (by implication, France), and the very disparate actions taken in response to contamination. "Everyone got under their own umbrella", said a Commission spokesman, and some umbrellas were big and others patchy.

The environment commissioner's objective in attacking national safety measures is thus clear: he believes there is a central coordinating role to be played by the European Commission in matters of setting nuclear safety levels and the rapid collection and dissemination of information across national boundaries in the ease of accidents. Thus Clinton Davies last week attacked, by implication, West Germany, Italy, the Netherlands, Belgium and others for failing to implement an EEC directive on "basic norms" for

Made in Japan label on launchers

Tokyo

Next week Japan takes its first big step towards independence from US rocket technology with the test launch of its new H-I rocket.

Throughout its 17-year history, the National Space Development Agency (NASDA) has depended on licensed US rocket technology to boost its satellites into orbit. Breaking with that tradition, the H-I has a domestically developed second-stage cryogenic engine, the LE-5. On its first test flight, a two-stage version will be flown; later flights will be of the full three-stage rocket. And, unlike its predecessors, the N-I and N-II, the rocket will also have a new Japanese-built inertial guidance system.

Scheduled to blast off on 13 August, the H-I will carry three inexpensive payloads into orbit; the Experimental Geodetic Payload (EGP), a hollow globe over two metres in diameter, covered in mirrors and laser reflectors, that will be used by the Maritime Safety Agency and the Geographical

Survey Institute for laser triangulation surveys; the Japan Amateur Satellite-1 (JAS-1) for ham radio enthusiasts; and a magnetic bearing flywheel to be tested in space before incorporation into future satellites. The total budget for the launch including the satellites is 16,000 million yen (about \$100 million).

From 1988 the rocket is planned to go into regular service placing communications, broadcast, meteorological and Earth resources satellites into geosynchronous orbit. But with a maximum payload capacity of only 550 kg, the H-I is still small by international standards, and by 1992 NASDA hopes to replace it with the H-II, a two-stage launcher, capable of boosting a 2,000 kg satellite into a geostationary orbit, that will be 100 per cent "made in Japan".

Although still not in the big space league, the H-II will allow Japan to compete in the international market for the launch of small to medium scale satellites in the 1990s.

David Swinbanks

emissions and radiation exposure, which had been due for ratification last April. Europe's principal nuclear states, Britain and France, are not in default on "basic norms", but according to a spokesman "most" of the 12 EEC nations have failed to implement another directive, on exposure to medical X rays.

Both radiation directives, agreed by the European Council of Ministers in 1984 (subject to ratification by national parliaments), are applications of the much older Euratom Treaty of 1957. This treaty is, in turn, one of the foundation stones of the European Communities and gives the European Commission wide powers to gather information and set standards of nuclear safety. The nuclear member states, in particular France, with nearly 70 per cent of its electricity demand met by nuclear power, are set firmly against such a role for the Commission. But in Brussels

it is felt that a clear, objective, international information system is urgently needed—otherwise the European public, including even the French, will lose confidence in nuclear power altogether. Last week Clinton Davies made a firm and specific proposal that such a system be set up, although he drew back from pressing for the wider powers that the Euratom Treaty would allow, but which for the moment seem politically inopportune.

As if to confirm the commissioner's views, the influential umbrella organization for European consumer associations. the Bureau Européen des Unions des Consommateurs (BEUC), which receives a small grant from the European Commission, also recommended such an international reporting system last week. In a 35-page report which collated official and published information on national responses to the Chernobyl disaster and its fallout, BEUC contrasted, among other things, the 3,700 becquerel per litre radiation level prescribed in France in milk with the 500 bq 1-1 upper limit in the Netherlands and Belgium, and the 20 bq 1-1 imposed during the Chernobyl affair in the German Länder of Hessen and

BEUC, with its large public backing through the consumer associations, also recommends in its report that the Commission adopt its full powers under the Euratom Treaty; that it set up a truly independent scientific committee to make recommendations on standards; that it prepare a European-wide contingency plan for any future accident, including one at a chemical plant; and that it develop a long-term post-Chernobyl research programme.

Robert Walgate

Soviet/West German cooperation agreed

Hamburg

WEST Germany and the Soviet Union have agreed on closer cooperation in science and technology. Foreign Minister Hans-Dietrich Genscher signed a framework treaty in Moscow two weeks ago which covers three sub-agreements on nuclear power, medical and agricultural research. Fifteen two-year programmes were agreed.

Then negotiations began in 1973, but soon came to a halt. Only when Chancellor Helmut Kohl met First Secretary Gorbachev in 1983 did both sides agree to continue the talks. A draft was ready in 1984 but in the new treaty the ministers add a note of their intention to work out a fourth,

additional sub-agreement on environmental protection.

The framework treaty is of particular importance in the light of Soviet efforts to make their nuclear power safe. The agreement includes clauses on exchange of information and scientists and the organization of meetings, exhibition and courses. Basic research may even be performed jointly in shared laboratories, but it is not yet clear what projects will be tackled. On the political side, the treaty is sure to help the progress of negotiations with East Germany on a similar treaty. Discussion began in 1973 but no agreement has been reached even after 27 meetings.

US-Japan trade

Truce agreed in chip war

Washington

Just minutes before midnight on 30 July, Japanese and US negotiators reached a comprehensive agreement on trade in semiconductors. Under the terms of the five-year agreement, the Japanese government will both help US semiconductor companies to increase their share of the Japanese market and stop Japanese companies from "dumping" chips on international markets. The US industry is well pleased with the agreement. But the industry knows that a key question remains; can it be enforced?

Reaching an agreement before midnight on 30 July was crucial. That was the statutory deadline for a Department of Commerce decision to impose permanent dumping duties on erasable programmable read-only memory (EPROMs). The Commerce Department had already made a preliminary judgement that Japanese manufacturers were dumping EPROMs — selling them at less than fair value considering their production costs — and chip importers have been posting bonds against possible imposition of duties. Under the agreement, both the dumping case against EPROMs, and a similar case against 256 kilobyte dynamic random access memory chips (256K DRAMS) with an 1 August deadline, will be suspended. In exchange, the Japanese government agrees to ensure its manufacturers sell products only at "fair market value". Also suspended is an unfair trading case being pursued by the office of the US Trade Representative, which could have resulted in sanctions against Japan.

To increase the US share of the Japanese semiconductor market, Japan will establish an organization to assist foreign manufacturers' sales efforts, and will also promote long-term relationships between US manufacturers and Japanese semiconductor users. While there is no specific target, the US market share in Japan is expected to increase to 20 per cent by the end of the five-year agreement. US sales at present account for 8–10 per cent of the Japanese market.

Another key element of the agreement, according to George Scalise of the Semiconductor Industry Association (SIA), is that US companies manufacturing in Japan will be given the same rights and privileges as Japanese companies, which is likely to increase the market share for the US industry.

In the week just before the signing of the agreement, Japanese manufacturers made a large number of sales to US customers. While the agreement on EPROM dumping became effective on 31 July, 256K DRAMS can be shipped to customers at any price agreed before 1 August until 15 September. After that, fair market pricing will prevail. But US industry spokesmen concede that a large number of chips can be delivered to US customers during that time. Sales of 256K DRAMs now account for 17 per cent of the total US semiconductor market.

To prevent future dumping, Japanese companies will provide data on pricing of EPROMs and 256K DRAMS to the Department of Commerce on a regular basis. The Japanese Ministry of International Trade and Industry will keep track of pricing data on other semiconductors, as well as products to be shipped to markets other than the United States. The United States

can request immediate 14-day consultations to resolve dumping questions and retains the right to initiate its own anti-dumping investigations that could result in the imposition of dumping duties. The issue of third-market sales, and the possibility that chips would be dumped in small countries for trans-shipment to major customers at cut-rate prices, proved especially divisive in the negotiations. Although Japanese companies never admitted to dumping during the negotiations. Michael Gadbaw of SIA says they nevertheless "promised never to do it again".

What gives US negotiators confidence that Japan will adhere to the terms of the agreement is the threat that the suspended dumping and unfair trade cases can be reinstituted. But many believe that it will take a lot of work to turn these commit ments into reality.

Technology journals

Time to learn Japanese

Washingtor

FEARFUL that US industry is not doing enough by itself to tap the voluminous output of Japanese scientific and technical literature, the US Senate is expected this week to agree to set aside \$1 million per year for efforts to make access easier. How the money will be spent has not yet been decided, but a possibility is that special representatives in Tokyo of the US Commerce Department will seek out the best from the Japanese literature and ensure that it is available in translation to US researchers.

Even supporters of the measure acknowledge, however, that the amount specified will do little to right the huge imbalance in the flow of technical information. The total number of US translators capable of handling difficult technical material in Japanese is small, perhaps only 200, with most of them working for one company. Japanese efforts to translate Western literature into Japanese, by contrast, are impressive: over 5,000 scientists and engineers are said to abstract routinely some 10,000 foreign and domestic journals, as well as other sources.

The Japanese Technical Literature Act directs the US Secretary of Commerce to redirect \$1 million from other Commerce Department activities to the monitoring and dissemination of Japanese technical developments. So far, the department has agreed to find only \$250,000. The act requires the department to consult businesses, professional societies and libraries in order to find out what is in most demand; it must, however, avoid offering material already sold by commercial companies.

A probable formula is that the Commerce Department's International Trade Administration will represent the Nation-

al Technical Information Service (NTIS also part of Commerce) in Tokyo, and will then offer the information culled to US industry and academic institutions for a nominal fee. NTIS already monitors some Japanese government publications, but spent only \$18,000 last year on translation. The future of NTIS is, however, uncertain; the federal government has proposed turning over the agency in whole or in part to the private sector, and NTIS staff fear they may never see the money The International Trade Administration. in contrast, already has ideas about what it would do with the promised \$250,000. produce another two of its in-depth reports on Japanese technology, four of which were produced recently for \$500,000 and were sell-outs.

By far the largest Japanese translating operation in the United States is the provate-sector Japanese Technical Information Service (JTIS) of Media, Pennsylvania, a subsidiary of University Microfilms. JTIS (which claims to employ most of the qualified Japanese translators in the United States) abstracts some 600 Japanese journals for its industry clients and offers full translations as requested. But at \$5,500 per year for a subscription to its abstract journal, sales have been restricted to major companies, with only 150 or so paid-up subscribers.

Justin Bloom, a former science adviser at the US Embassy in Tokyo, says that it JTIS's service fails to prosper it will show there is "no demonstrable US interest" in access to Japanese literature. But he is sceptical about the new act, describing it as "laudable in principle but meaning little in practice". Bloom says that in Tokyo, even with a staff of 22, he was hardly able to make an impact in monitoring Japanese technical literature.

European biotechnology

Parliament giving up alcohol

THE giant Italian food and agricultural company Ferruzzi is set to fight back after the European Parliament struck a blow against its plans to convert Europe's grain mountain into fuel alcohol. The plan, according to Ferruzzi, would create jobs, be environmentally benign, and give farmers a new deal. But, says a report adopted by parliament before the summer recess, the project would kill jobs in the oil industry and could produce far more pollution (in the form of biological oxygen demand) than all Europe's sewage. In Brazil, where a similar project has been under way since the 1970s, up to half a million jobs have been created, 80 per cent of them unskilled, says the report. There are no studies available, however, to indicate the possible impact in Europe, where educational and skill levels are higher and where technology is often cheaper than labour.

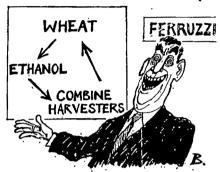

Ferruzzi, the company whose proposal led to the reports, was recently referred to the British Monopolies Commission for its thinly disguised attempt to take over British Sugar, the UK beet monopoly. But this has been only the latest event in the saga of the expansionist group, which already controls most of the sugar production in Italy and has a controlling stake in the leading French sugar manufacturer Beghin-Say. Control of British Sugar would give Ferruzzi one quarter of the sugar market of the whole European Economic Community (EEC). Through its alcohol project, the company has shown an almost equal interest in grain.

Ferruzzi's grain-to-alcohol plans would leave Scotch whisky producers standing. The group has proposed 12 conversion plants, costing upwards of \$560 million, and designed to take 15 million tonnes of cereals a year for conversion to alcohol.

The Ferruzzi plants would be built in France, where 94 per cent of Europe's grain surplus is grown (according to the European Parliament report). Naturally enough, the French farm minister François Guillaume, an ex-farming trade unionist, supports the Ferruzzi plan, and so do most of the French members of the European Parliament, but this was not enough last month to reject the parliamentary report, which itself rejected the production of bioethanol from raw materials "in present market conditions". The resistance to a large, precipitous bioethanol programme cut across all countries (other than France) and all parties; and although the parliament has little real power, its position will certainly give political weight to the European Commission (the EEC secretariat) which has also rejected the Ferruzzi proposal.

The principal reason for rejection is that the project is drastically uneconomic without vast EEC subsidies. Ferruzzi's plans would require grain at world market prices. The present EEC subsidy to grain farmers, guaranteeing the sale of their grain at inflated European prices, would therefore have to continue. Moreover, this would still not bring the alcohol down to saleable prices as a fuel additive, where it could displace either petrol itself or the

In other words, perpetual motion!

new lead-free anti-knock agents. At present prices of oil and of anti-knock agents, governments would also have to offer tax reductions on any alcohol-containing petrol sold, the Ferruzzi group says.

Such arguments would seem to rule the whole proposal out of hand—and certainly the canny Dutch ex-economics minister, Fran Adriessen, who is now European Commissioner for Agriculture, rejects it—if it were not for the renowned strength of certain European agricultural lobbies, particularly the French. Ferruzzi's president, Dr Paul Gardini, has promised that he will not let the issue rest. The possible carcinogenicity of some proposed

anti-knock agents is one new line to try.

Meanwhile, therefore, the vote at the European Parliament is just one further move in the game, which is continuing through a \$200,000 study on the social and economic impacts of a European gasohol programme. This independent report should be ready in draft by November, when it could in principle receive attention by the Commission during the British presidency of the European Council, the Commission's decision-making body. But Britain, committed to reforming the overproductive and costly Common Agricultural Policy is thought to see European gasohol as yet another "black hole" of European subsidy, and will not aid the Ferruzzi project even if the study recommends it.

The European Parliament did not reject the development of bioethanol plants on a 🔍 smaller scale, and at smaller rates of subsidy, than envisaged by Ferruzzi, however. Small plants could be of use to remote rural areas and parliament recommended Commission support for research and pilot projects along these lines. On the whole, however, the European Parliament, which has a higher representation of scientists than probably any national assembly in Europe, is of the opinion that the Ferruzzi plan would do damage to the more cautious and reasonable plans of the Commission to introduce biotechnology to European farms under its proposals for "stimulating agro-industrial development". These, involving pilot studies from post-research field trials of new crops to biotechnology-based processes, are not billed to remove the European food surpluses next year, but could, Commission officials hope, sow the seeds of a new European agriculture. A failed bioethanol programme could set such proposals back by years. Robert Walgate

Transplant donor held up by red tape

When Dr Robert Gale, the bone-marrow transplant specialist, flew to Moscow in May to treat the victims of the Chernobyl disaster, he took with him an essential piece of equipment for sorting cells, developed at Israel's Weizmann Institute. He also took an urgent request for help from an Israeli biologist, Michael Sherman, who himself needs a bone marrow transplant. Ironically, until he developed leukaemia last year, Sherman was employed at *Interyeda*, a commercial company established to develop innovations based on research conducted at the Weizmann Institute.

Michael Sherman is an emigrant from the Soviet Union, who settled in Israel some six years ago. The only possible related donor would be his sister, who still lives in Moscow. In February, as soon as she heard of her brother's illness, she immediately applied to OVIR, the Soviet passport department, for permission to go to Israel to donate the necessary marrow. There was no immediate reply, but after Gale's visit, the sister and her husband and children were called to the OVIR office. They were informed that a temporary visit to Israel on a Soviet passport was impossible due to "bureaucratic difficulties", and were advised to apply for permanent emigration to Israel. On 2 July, therefore, they filed the appropriate papers.

Shortly afterwards, Sherman says, "unpleasant things" began to happen. His sister was demoted to a lower-paid job, and, now "they are examining the possibility of firing her". It now appears, he says, that OVIR is treating the case as a routine request to emigrate, with all the delays that involves. And that, in Sherman's case, could well be too late.

Vera Rich

Success breeds privatization

THE British government is to go ahead with its plan to sell off its institutes for the development and marketing of new varieties of plants. The government has long seen the sale as politically desirable, given its philosophy that the role of the private sector should be expanded. But it was only last week that a merchant bank confirmed that the sale will also be financially profitable.

The two organizations to be sold, the National Seed Development Organization and the Plant Breeding Institute (PBI), might seem to form a natural couple. PBI, belonging to the Agricultural and Food Research Council (AFRC), runs large-scale programmes in plant breeding which have produced nearly all the new varieties sold by the National Seed Development Organization. This has been a profitable business, generating £4.65 million for the government last year. Given that support for plant breeding research at PBI cost just £2.5 million last year, the institutions are bound to seem an attractive buy.

In the short term, researchers in plant breeding may benefit from privatization. In recent years, they have suffered the same cuts in research council funds that have been felt elsewhere and one breeding programme, for Triticalae, the family that includes grasses and cereals, came close to being abandoned. Private industry should provide funds more closely related to profitability. But there must be some

The new owners want you to concentrate on improving coca-leaf yields...

doubts about the longer term. Before privatization, PBI's molecular genetics and cytogenetics sections will be split off and combined with other AFRC institutes to form a new Plant Sciences Institute. That, according to PBI's director Professor Peter Day, will threaten a much admired quality of the institute, its ability to "couple disparate activities" under one roof. Whether it makes sense to remove the plant breeding part of the institute from its more basic molecular genetics research section just when the impact of molecular genetics is beginning to be felt must be a matter of controversy.

Much will depend on the buyer. The favourite is the Agricultural Genetics Company, a private company partly own-

ed by the British Technology Group that was set up in 1984 and given first option to develop plant biotechnology discoveries made at AFRC institutes. Although the company is well placed to ensure that fruitful cooperation between the privatized institutes and the research laboratories of AFRC continues, it lacks size. It is still a small organization with fewer than 30 staff, based at Cambridge's Science Park. Big multinational agricultural companies are bound to recognize the appeal of the two institutes and to be able to offer far more money for them. The only reservation they are likely to have is that the Agricultural Genetics Company has already gained the right to commercialize

NEWS:

many of PBI's discoveries. Whether the government will accept the Agricultural Genetics Company's view that it is "the natural vehicle for maintaining the integrity and future development" of the institutes within the private sector should be decided within the next few months.

491

The future of the remaining "plant sciences" fragment of PBI is unclear. The new Plant Science Institute will be completed by the addition of the John Innes Institute, the Unit of Nitrogen Fixation at the University of Sussex and a small part of the Rothamsted Experimental Station. But no provision has been made to bring the various parts together at one site the "institute" will be more of an administrative convenience. Again, it is not clear if AFRC will itself profit from the sale of PBI or whether the proceeds will accrue directly to the Treasury. Alun Anderson

US-Soviet exchange

Relations thaw in the far north

Washington

An agreement between the University of Alaska at Anchorage and the Siberian Branch of the Soviet Academy of Medicine to study problems of human adaptation to circumpolar living was endorsed by a Soviet delegation visiting Washington last week. But last minute uncertainty about official Soviet participation pointed up the fragility of US—Soviet relations.

For five years, Ted Mala, associate professor of health sciences at the University of Alaska, has been trying to work out an agreement with Siberian scientists to study health issues relating to life in the far north. Mala wrote to Soviet leader Mikhail Gorbachev, who responded favourably to his suggestions for cooperation, and arranged meetings with officials of the Soviet health ministry as well as the medical workers' union. The US-Soviet Exchange Initiative Office, established after last winter's summit meeting between President Reagan and Mr Gorbachev to encourage people-to-people exchanges, supported Mala's efforts.

Last week an agreement between the University of Alaska and the Soviet Ministry of Health was due to be signed through the US-Soviet Exchange Initiative Office, and Mala was summoned from Alaska for the signing ceremony. But on arrival in Washington, the Soviet delegation declined to sign a formal agreement, saying the exchange could take place only under health agreements in effect since 1972. The delegation did sign what amounted to a memorandum of understanding saying that Mala could visit the Soviet Union to complete arrangements for the exchanges, but formal plans would have to be approved next by the US-USSR Joint Health Committee formed under the 1972 agreement — a committee that has not met for seven years.

Although health exchanges between the United States and Soviet Union have never stopped, there has been a slowing down in the past seven years. In 1972, the two countries signed two self-perpetuating agreements to cooperate in health sciences. The Joint Health Committee. consisting of senior health officials from both countries, met each year, but the United States cancelled the 1979 meeting following the Soviet invasion of Afghanistan. In recent years the climate has been changing, and a 1984 speech by President Reagan called specifically for the renewal of cooperation in the health sciences, a call given added impetus by last year's summit meeting.

A three-step plan has been worked out to improve relations. Surgeon General C. Everett Koop and Dr James Mason, director of the Centers for Disease Control, will visit the Soviet Union in October to discuss cooperation in the realm of public health. James Wyngaarden, director of the National Institutes of Health, will make a similar journey in November to discuss biomedical cooperation. Finally, the Joint Health Committee is to meet again next spring after nearly eight years.

As Mala's proposed exchange is strictly a private agreement between the University of Alaska and the Soviet Institute of Medicine, the US government has no control over what Mala plans to do. But the Soviet Union is placing things on a government-to-government basis. Harold Thompson, deputy director of the Office of International Health at the Department of Health and Human Services, says the US government is not happy with that arrangement, but does not feel that it should be allowed to interfere with exchanges.

Joseph Palca

US space

Continuing problems all round

Washington

THESE are trying times for US space scientists. The space shuttle is grounded until at least 1988, and when flights resume, competition for cargo space will be fierce. While there is discussion of launching scientific missions on expendable launch vehicles (ELV), for the time being nothing is decided. Planetary scientists are among the hardest hit. At the end of last month, they learned that new weight restrictions mean that neither the Comet Rendezvous Asteroid Flyby (CRAF) mission nor the Saturn orbiter (Cassini) can fly aboard the shuttle. This news follows a decision to abandon the shuttle/Centaur upper stage that would have been used to take Galileo to Jupiter (see Nature 321, 800; 1986). Bruce Murray, professor of planetary science at California Institute of Technology (Cal-

Moustafa T. Chahine—chief scientist at JPL. tech), puts it bluntly, "the US planetary program has collapsed":

For the Jet Propulsion Laboratory (JPL) in Pasadena, the delays will be especially difficult. JPL is run by Caltech for the National Aeronautics and Space Administration (NASA). Although JPL is engaged in a variety of projects from remote sensing to astrophysics to defence-related research, Solar System exploration has been its bread and butter. Fully 20 per cent of JPL's 1985 budget was spent on three planetary probes, Galileo, Voyager and the Venus radar mapper Magellan.

The uncertain future is beginning to take its toll on the staff of JPL, says Moustafa Chahine, its chief scientist. Chahine says morale is still high from Voyager's Uranus flyby last January, but senior scientists now face tough decisions. The median staff age at JPL is 42, and scientists are at a crucial juncture in their careers. "Would you commit yourself to 10 years of uncertainty?" asks Chahine rhetorically. Although nobody has yet left JPL, Chahine is certain that some will do so in the coming months.

That no major missions can be launched for at least three years does not necessarily have to be a drawback for planetary science, maintains Chahine. With a strong commitment from NASA, JPL would have no trouble assembling a team to plan new missions. Were planning to begin in 1988, a reasonable launch date would be the early 1990s, by which time either the shuttle or some other launch vehicle should be back in operation. Working on long-term projects is something JPL scientists are familiar with. What is needed, says Chahine, is a demonstration from NASA, in deed not just word, that planetary science will not be forgotten as NASA plans for the future.

JPL is not the only NASA centre to have taken a body blow from the delays in the space programme. Noel Hinners, director of the Goddard Space Flight Center in Greenbelt, Maryland, says Goddard also must cope with uncertainty. "Mentally, things are on hold", says Hinners. If the launch delays for Goddard projects such as the Gamma Ray Observatory or the Cosmic Background Explorer are of the order of one to two years, Hinners believes most key people will stay with the projects. But a delay of five years is a different story. Even keeping a launch team together for two or three years is tough, and Hinners reckons people will have to be laid off.

While the Hubble Space Telescope (HST) is in the same boat as the other major satellite launches, the delay seems to be less troubling to Garth Illingworth, deputy director of the Space Telescope Science Institute. He maintains that optical astronomers have never had a chance to become dependent on space-based observations, and can get by with existing ground facilities. "We are not really as subject to the feast or famine as the planetary people", he says.

James Welch, Space Telescope project director for NASA, agrees that principal investigators are unlikely to leave the project. But keeping the engineering team intact will not be easy, Directing routine maintenance while the satellite is in storage is not a stepping stone to career advancement. One challenging engineering problem has, however, recently cropped up for HST. NASA's heightened awareness of safety issues has prompted a re-evaluation of the natural frequency of satellite subsystems. If they coincide with the frequency of shock waves generated by the shuttle, there could be serious problems. Determining these frequencies is not easy, says Welch.

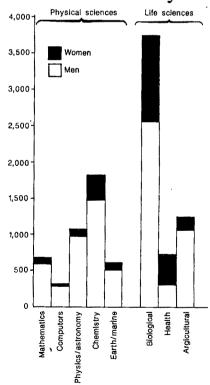

Although NASA and the Reagan administration have not yet enunciated a clear policy on alternative launch vehicles

to the shuttle, most members of the space science community see a new fleet of expendable launch vehicles as crucial. Tom Donahue, chairman of the National Academy of Sciences Space Science Board, told Congress last month that he supports the use of the Air Force's new Titan 34D7 to launch deep space missions. Donahue favours moving to the Titan 34D7 to launch Galileo, Magellan and Ulysses (the joint mission with the European Space Agency to study the Sun's polar region) even if it means postponing acquisition of an orbiter or slowing down work on the space station.

If there is any bright side to the current upheaval, Murray believes it may be the study of Mars. The Mars Observer, the first of a series of low-cost planetary probes, is scheduled for a 1990 launch, and could still make use of the shuttle. Murray says the Soviet Union is planning two major missions to Mars in the next five years, and there have been non-governmental discussions about a joint United States/Soviet Union mission. These factors may make Mars programmes attractive candidates for new funds.

US doctorates by sex

THE numbers of doctorates awarded to men and women in the United States in 1985, taken from a report from the National Science Foundation division of science resource studies. In total 4,531 doctorates were awarded in physical sciences (3,817 to men, 714 to women) compared with 5,748 in the life sciences (3,893 men, 1,855 women).

New telescopes

Shining mirrors at Apache Point

Washington

USING a new mirror technology and a new design, a consortium of five universities is planning to build a 3.5-metre telescope in New Mexico's Sacramento Mountains. With a recently awarded grant of \$3.74 million from the National Science Foundation (NSF), the Apache Point Observatory is scheduled to begin operation in 1988.

Apache Point's mirror is a smaller version of the type of mirror likely to be used for the National New Technology Telescope (NNTT). It is cast using borosilicate glass and spun as it is cast, allowing a closer first approximation of the desired parabolic shape. The new techniques result in lighter and less expensive mirrors, bringing the cost of observatories the size of Apache Point to a level manage-

More ocean dives

Tokvo

THE US submersible Alvin is scheduled to make its first visit to Japanese waters in 1987. Scientists from the United States and Japan have agreed plans for at least 85 dives to investigate the back- and fore-arc regions of the western Pacific.

Dives will be made in three areas; the Mariana Trough, a back-arc spreading centre, the Mariana fore-arc region which overlies the subducting Pacific Plate and the Sumisu back-arc rift northwest of the Ogasawara Islands.

Among the features to be investigated are a methane plume billowing up to 700 m above the floor of the Mariana Trough; diapiric seamounts bulging out of the seafloor of the Mariana fore-arc region; a chain of volcanoes that trends across the back-arc basin from the Northern Mariana Arc; and the Sumisu Rift which is thought to be a modern analogue of the setting for the Kuroko massive sulphide ore deposits on the Japanese mainland.

Funding for the project, which will run up a bill of a few million dollars, will be covered almost entirely by the US side.

Follow-up investigations of the survey area by the Japanese submersibles Shinkai 2000, and, when completed, Shinkai 6500, are expected to be made in the near future according to Hiroshi Hotta, director of the Deep-Sea Research Department of the Japan Marine Science and Technology Center (JAMSTEC), who will participate in the Alvin survey. In a recent review of policy, JAMSTEC decided to devote attention to the spreading ridges and rift basins in close proximity to Japan, such as the Okinawa Trough and Sumisu Rift. Also, in future, foreign scientists will be allowed to board Shinkai 2000. **David Swinbanks**

able by a small research consortium.

The five universities are not all equal partners in the project. The University of Chicago and the University of Washington will both contribute 31 per cent of the project costs, Princeton University and New Mexico State University 16 per cent and Washington State University the remaining 6 per cent. Bruce Margon of the University of Washington, chairman of the Astrophysical Research Consortium formed by the universities to build Apache Point, says viewing time will be allocated in accordance with contributions. Margon estimates the total cost of the project will be \$10 million.

Using private funds to build large observatories is a new trend. Several university groups have announced plans to build 7.5-metre telescopes, and the Keck Telescope, a 10-metre segmented mirror telescope that will be operated by California Institute of Technology and the University of California, is already under construction in Hawaii.

Several factors make Apache Point attractive. The observatory is the first designed for complete remote operation. Margon points out that this allows users to wait for appropriate conditions without having to make a pilgrimage to New Mexico. It will also be possible to divide a night's observation among astronomers at different institutions.

The performance of Apache Point may well exceed that of larger telescopes for certain problems. Keeping the structure housing the telescope to an absolute minimum will reduce atmospheric distortion caused by the heat from the observatory's own instruments. Sacramento Peak is also one of the darkest points in the United States, making it an attractive spot for observing extremely low light objects.

Perhaps most alluring to consortium members is that once built. Apache Point will be theirs to use as they please. Observing time is oversubscribed at the Kitt Peak National Observatory in Auzona and Cerro Tololo Inter-American Observatory in Chile. At Apache Point, says Margon, users will be able to tackle longer term and speculative projects

Joseph Palca

Timber trade

A little hope for tropical forests

AT long last the world has an international forum that could help avert the total destruction of tropical forests. All the major tropical timber producing and consuming nations agreed in Geneva last week to put into operation the International Tropical Timber Agreement. Among its clauses are those aimed at "sustainable utilization and conservation of tropical forests and their genetic resources, and at maintaining the ecological balance . . .".

The agreement has been twenty years in the making and has been held up for more than a year by a squabble over the location of its headquarters. Only after a fresh meeting broke up in disarray was agreement finally reached: the headquarters are to be established in Yokohama and its executive director is to be Mr Haji Freezailah, deputy director-general of forestry for Malaysia. This arrangement neatly ties together the world's biggest tropical timber producer, Malaysia, and the biggest consumer, Japan. But argument is continuing over the budget for the new organization and nobody yet knows how effective a body it will be.

The UN-sponsored agreement does not establish a cartel and has no powers to fix prices or to regulate exports. But it does provide a talking shop for 41 nations that between them account for 95 per cent of the world's trade in tropical timber and, uniquely for a trade agreement, it has among its principal goals the preservation of tropical forests so that they may be

managed as a renewable resource. Other aims, also intended to benefit timber producers in the developing world, are to promote research and development in tropical forest management and utilization and to encourage the processing of timber in producing countries to promote their industrialization and export earnings.

The Scandinavian countries have taken the lead in introducing into the agreement clauses aimed at protecting tropical forests. Voting rights have been equally distributed among producer and consumer countries and if a majority can be found there is every chance that these clauses can be translated into action. The chief obstacle is likely to be lack of money Several thousand million dollars need to be spent to halt tropical deforestation and the producer countries naturally feel that the bulk of the burden should be borne by the wealthy consumers. As a practical first step, the World Wildlife Fund is urging the appointment of an experienced forest ecologist to help run the agreement and prevent forest disasters; it also wants at least \$5 million to be set aside for conservation projects in the short term and says that prices for tropical timber should include the cost of reforestation, conservation and research on sustainable management. It is likely to be next spring, at the earliest, before the organization announces its initial budget and there is any indication of how successful it might be.

Alun Änderson

Academic oppression in Chile

Sir—On the afternoon of 1 July, we witnessed the siege and assault of the building of the School of Medicine of the University of Chile by a combined force of the military and the police. Military vehicles and troops first circled the quadrangle where the School of Medicine and its teaching hospital are located and then occupied both buildings. Among other actions, we saw a group of soldiers, armed with automatic weapons and with their faces painted black in combat camouflage, as they took twenty students as prisoners and made them lie face down on the floor of the hall of the School of Public Health.

Afterwards, another seventy students tried to take refuge in the classrooms of the department of physiology. The police broke in, took them out, and lined them up in the hall in order to arrest them. At that point, a professor implored the many faculty members gathered there to do something to prevent the students from being taken away. Her brave attitude created a vividly emotional atmosphere that allowed the dean of the faculty to persuade the police not to proceed to further arrests.

This episode was only one of the many assaults in the past weeks by combined military and police forces in several faculties of our university that have ended with violent arrests of students. These assaults typically include tear-gas bombing, the breaking into the university yards of heavily armed soldiers and vehicles and, in some cases, the destruction of installations and laboratory equipment. As a matter of fact, the action on 1 July was taken because the students were peacefully protesting against the arrest of 118 of their fellows, including the president and other members of the student council, which had occurred the day before inside the university main building. The student leaders were arrested invoking an article of the new Chilean constitution that allows special action to be taken against "terrorists that cause public alarm".

Student demonstrations have been aimed at ending the overt government intervention suffered by our universities since the 1973 military takeover; at the same time, the professors of the University of Chile have recently asked, through a referendum, for the resignation of the present principal of the university, a serving major general of the Army, and the election by the academic community of academic authorities.

On 2 July, Carmen Gloria Quintana, an 18-year-old student of the University of Santiago, and Rodrigo Rojas, a 20-yearold Chilean who had recently arrived from the United States where he was a resident, and who was collaborating as a computer programmer at the department of physiology of the University of Chile School of Medicine, were found with burns that extended over 60 per cent of their body surface. This event has been well documented by the world press.

On 10 July, the government arrested some prominent leaders of social institutions, who had concurred in the creation of an Assembly of Civilians, asking for the return of the country to a democratic regime. Among those arrested were Dr Juan Luis Gonzalez and Dr Francisco Rivas, president and secretary of the Chilean College of Physicians, and Professor Patricio Basso, president of the Association of Professors of the University of Chile.

We think that these events should stimulate reflection and action by the international academic community. In experimental sciences, insights of widespread relevance are obtained not from the observation of phenomena in their usual context but rather from taking them to extreme conditions. In Chile, the relationship betwen university, society and the political regime has been brought today to a grotesque extreme.

AGS vindicated

SIR-In recent months it has been widely reported that scientists at Advanced Genetic Sciences, Inc. (AGS) "knowingly falsified" data in an application to the US Environmental Protection Agency (EPA). EPA has now "concluded that there is no information to indicate that (AGS) knowingly falsified its application".

The original allegations of data falsification surfaced during a congressional subcommittee hearing, and were based upon an unsigned two-page handout and an 8 × 10 inch photograph. These documents were supposed to demonstrate inadequate experimental design and plant pathogenic effects of the recombinant Pseudomonads, and were purportedly the subject of an AGS cover-up. EPA now accepts this "evidence" was inaccurate.

Unfortunately our vindication from the charge of falsification will not automatically reverse the damage that has been done to the reputations of individual scientists at AGS. The uncritical reporting of these allegations has caused much damage; scientific fraud should not be taken so lightly.

An article in Nature (320, 472; 1986)

referred to the allegations as though they were established fact, perhaps because of a misunderstanding of the operating procedure of EPA's Office of Enforcement and Compliance Monitoring. The process of developing an "administrative complaint" is interactive and EPA's initial charges were apparently made more in the spirit of prosecutor than in the role of judge. In fact, the charges of data falsification were not supported by EPA's own data audit, the basis for the final retraction of those charges, which had already been completed when the initial complaint was

How and why did this situation lead to the publication of misleading, unjust and damaging reports? Somewhere between the deed and the reporting, the process of disseminating information went badly awry. It should be of concern to everyone when the news reaching the scientific community becomes subject to distortion by politics and sensationalism. It should be of concern to everyone that our case demonstrates the success of a frightening weapon the gratuitous accusation of fraud.

J. Bedbrook, P. Dunsmuir, J. LINDEMANN, T. SUSLOW, G. WARREN Advanced Genetic Sciences, Inc., 6701 San Pablo Avenue,

Oakland, California 94608, USA

• We are glad to clarify that the allegation of falsified data appeared only the EPA's formal complaint, not in its announcement that AGS would be fined \$20,000 (later reduced). But should not EPA be more careful about giving currency to allegations such as these, especially when it knows them to be unfounded? -Editor, Nature.

Parapsychology

SIR—Elitzur¹ criticizes Marks³ for having omitted "representative" works. I know of no work that could be acceptable as a case for parapsychology. As for the extraordinary instrumental sophistication proudly presented, my question is why such a complicated mess is necessary for the basically rather simple claims of psi such as telepathy, telekinesis and so on. If they existed, their demonstration should actually be simple.

There is an explanation for the complexity. The more complicated the experiment, the more likely it is that it will have errors that will be attributed to psi. At the same time, it becomes easier deliberately to introduce errors and more difficult and time-consuming for sceptics to find them. If anything, the mentioned counterhypothesis coincidence, artefact, selfdeception and fraud become more likely.

Hanover highlights all the latest developments

and industrial applications

in the field of biotechnology

From its very inception **BIOTECHNICA** Hanover has established itself as Europe's leading forum for research, development and practical applications in the field of biotechnology. The basis for the unprecedented success of BIOTECHNICA is two-fold. Firstly, the excellent program of symposia, workshops and lectures held by internationally renowned experts. And secondly, the user-oriented exhibition presented by leading manufacturers and research institutes.

The international congress – a meeting-place for experts

On three successive days, 16 internationally renowned experts will deliver papers on the application of biotechnology in the following fields:

Medicine/pharmacology

e.g. diagnostics and various approaches to therapy following cardiac infarction

Food production/ agriculture

including the optimization of agricultural produce and quality control in foodstuffs

Environmental protection

from biological methods of combating air pollution to the treatment of sewage

Seminars and workshops – a spotlight on research and its practical application

Research institutes, universities and leading manufacturers will utilize the comprehensive parallel program of talks, symposia and workshops in order to present their latest research findings, products and processes. Hanover illustrates how research findings can be transformed into marketable industrial processes and products.

In a series of special seminars organized by the European Community, BIOTECHNICA'86 will also present the most important results of the biotechnological research projects funded by the EC.

The 3rd US Seminar for Biotechnology, organized by the US Foreign Commercial Service, will also be held on all three days of BIOTECHNICA'86.

The exhibition – geared to industrial applications

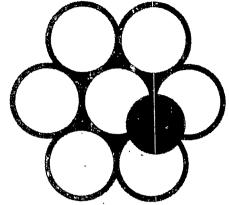

Over 200 research institutes and commercial firms will exhibit at BIOTECHNICA'86. The exhibition will highlight biotechnological processes and products, the latest developments in laboratory equipment and techniques, as well as new production technology. It's no surprise, therefore, that in 1985 some 3,500 professional visitors from 27 countries attended this comprehensive display.

At BIOTECHNICA Hanover'86 you can find out all you want to know about every major aspect of hiotechnology.

New ways with quasi-crystals While theorists continue to brood about the properties of quasi-crystals, experimentalists have begun

to simulate them in the laboratory to tell how they behave.

WHETHER the unexpected fivefold geometrical symmetry of the manganesealuminium alloy MnAl, springs from an underlying quasi-crystalline structure, from twinning on a microscopic scale as Linus Pauling says (see *Nature* 317, 512: 1985) or from a quite different phenomenon not yet identified, the whole idea of fivefold symmetry has enlivened several groups of people. That the theorists should have jumped in the new pool feet first is not at all surprising, which is why it is a little shocking that there is still no straightforward way of writing down a formula that will specify which points in three-dimensional space are the permitted vertices of a quasi-crystalline lattice. (The best approach is still to suppose that a three-dimensional quasi-crystal is the projection of a six-dimensional lattice on a three-dimensional surface.) But now the experimentalists have joined the fray, with entertaining consequences.

That fivefold symmetry is unattainable in an infinite regular crystal lattice has been known since the allowable symmetries of crystal lattices were first enumerated in the nineteenth century. The quasi-crystal explanation of the MnAl., alloy, whose strange symmetry was first recognized by Schachtman, remains essentially that suggested more than eighteen months ago by D. Levine and P.J. Steinhardt (Phys. Rev. Lett. 53, 2477; 1984). A quasi-crystal is not a regular lattice in which all vertices can be reached from all others by displacements represented by integral multiples of some basic set of vectors. Instead, the argument goes, the directions of the lattice bonds drawn between nearest neighbours in the crystal lattice take only a finite number of values, but the distances between successive vertices along a line, far from being equal, as in a regular crystal, may take one of two (or more) values which are, of necessity, incommensurate - their ratio is an irrational number. In two dimensions, the prototype of a quasi-crystal is the Penrose tiling of the plane, a kind of party trick by which a plane surface can be filled by rhombi of two distinct shapes yielding local fivefold symmetry. In this case, the crucial irrational number is the old Greek golden mean, half the square root of 5 plus 1.

How do experimentalists weigh into such a field? Here is a neat example, based on the familiar observation in superconductivity that the magnetic flux within a sufficiently small superconducting loop will ideally be quantized in the sense of being an integral multiple of the elementary quantity hc/2e, where h is Planck's constant, c the velocity of light and e the charge of the electron. Only integral multiples of this magnetic flux are compatible with the condition that the superconducting loop carries no electric current. The origin of the condition is the requirement that the phase of the wave function describing electrons in the superconductor should be unambiguously defined.

Now a six-person group based mainly at the University of Pennsylvania but including Levine (op. cit.) has devised a clever experiment to show that magnetic fields can tell the difference between lattices that are regular and those that are merely quasi-crystalline (A. Behrooz, et al., Phys. Rev. Lett. 57, 368; 1986). What this group has done is to build a pair of twodimensional arrays of aluminium wires merely 50 nm in diameter, one of which is a quasi-crystal of holes in one dimension, the other almost a Penrose tiling. The group has then measured the superconducting properties of this array in the presence of magnetic fields of different strength with the objective of telling how quanta of flux are distributed among the differently shaped holes of the lattice.

Others have previously set out to tell what happens when regular (not quasiperiodic) superconducting meshes are immersed in a magnetic field. If the total amount of flux, supposed uniform, across the mesh is an integral number of flux quanta, no electric current need flow in any of the wires so as to ensure that the phases of the electron wave functions are well defined. One of the simplest ways of recognizing that state of grace is to measure the temperature at which the superconductive transition takes place. If the temperature is identical with that of the superconducting phase transition in the absence of a magnetic field, the inference is that the flux through each and every hole in the mesh is an integral multiple of the flux quantum. Otherwise the transition temperature will be reduced. Behrooz et al. refer to earlier results showing that when the total flux through a regular mesh is less than enough to provide one flux quantum through every hole, the transition temperature is most nearly normal when the field is enough to endow each hole in the mesh with a rational (as distinct from irrational) fraction of a single I flux quantum.

That is an obvious starting point for the experiments now described. The simplest trick is to make a mesh from 50 nm aluminium wires which are regularly spaced in one direction but whose spacing in the orthogonal direction is that of the Fabonacci sequence, whose spacings are related by the irrational golden mean. For practical purposes, there are holes of two different sizes whose areas are irrationally related to each other. The experimental result is striking, even startling. The temperature of the superconducting transition is most nearly normal when the average magnetic flux through each hole amounts to a number of flux quanta which is a power of the golden mean. The inference is that the most energetically favourable distribution of the magnetic flux is one on which as many holes as possible are threaded by integral numbers of flux units, which is what would be expected. It is nevertheless remarkable that it should in principle be possible to measure the irrational ratio of the dimensions of the mesh simply by measuring the transition temperature as a function of total flux through all the holes.

Similar results have been obtained with a network analogous to the Penrose tiling of the plane, but where the characteristic irrational ratio is the square root of 2 (Forgivably, the authors say that they were unable to make a true Penrose tiling with their microfabrication apparatus. which is nothing to be ashamed of: they managed 20,000 holes of two different shapes related by the square root of 21 Again the most favourable threading of the total flux through the different holes is that determined by the irrational number The principle is merely that the best configuration is that when the quantum condition is most often satisfied. What the practical applications will be is anybody's guess, but there could hardly be a more vivid proof of the quantization of magnetic flux.

As it happens, a calculation of a more general system of this kind, a randomly organized superconducting network, has been produced by two Argentinian physicists, J. Simonen and A. Lopez (Phys. Rev. Lett. 56, 2649; 1986). Again, the conclusion is that integral numbers of flux quanta are energetically favoured. Meanwhile, experimentalists are busily studying other quasi-periodic structures. Obviously there is a whole new world to explore. John Maddox

Astronomy

First X-ray-ionized nebula

from A.C. Fabian

The hottest objects in a galaxy, the binary X-ray sources, should produce the most highly ionized nebulae. Despite extensive calculations of the ionization state of gas around X-ray sources (McCray, R. et al. Astrophys. J. Lett. 311, L29; 1977), no such nebula had been found until M.W. Pakull and L.P. Angebault studied the Large Magellanic Cloud carefully, as they describe elsewhere in this issue (Nature 322, 511; 1986).

Spiral and irregular galaxies are dotted with nebulae excited by hot stars. The H II regions are ionized by the ultraviolet radiation from massive main-sequence stars and glow mainly through recombinationline radiation. The even hotter cores of evolved stars that have recently ejected their outer envelopes, the planetary nebulae, ionize substantial amounts of helium as well. Visible radiation from planetary nebulae give an estimate of the ultraviolet radiation field, and thus surface temperature, of hot stars. In principle, this is a relatively simple deduction if it is assumed that all the photons capable of ionizing gases such as hydrogen do so, and that the resulting photon luminosity in some recombination line can be estimated from the observations.

The major problem in the search for nebulae around X-ray sources is that they tend not to be in dense gas environments, so the luminosity of the nebulae is very low. Massive main-sequence stars, by contrast, are young and embedded in dense star-forming clouds. Moreover, planetary nebulae create their own dense surroundings in the ejected stellar envelope.

The X-ray ionized nebula discovered by Pakull and Angebault, LMC X-1, was the first X-ray source found in the Large Magellanic Cloud and is securely identified by them with an 07 III-V star. The star appears to be surrounded by a nebula of radius 5 pc that emits visible lines of hydrogen and ionized helium as well as of doubly ionized oxygen. The He II emission is simply explained by the recombination of He III ionized by extreme ultraviolet photons of energy greater than 54 eV. These photons imply a much harder spectrum than any normal star and are consistent with the X-ray source. The centring of the emission on the 07 star identifies it, or rather its binary companion, as the X-ray source.

The extreme ultraviolet spectrum of LMC X-1 is of particular interest because the source is a black-hole candidate. Pakull and Angebault estimate that the spectrum is flat below the X-ray observed photon energies of ~1 keV down through

the otherwise invisible extreme ultraviolet to the ultraviolet. This could be the thermal black-body emission from an accretion disk. The spatial extent of the surrounding He III zone is ~10 light years and so presumably indicates that the source has maintained that spectrum and luminosity for at least the past 10 years.

LMC X-1 is an unusual black-hole candidate as it seems to be stuck in a 'high-state' (White, N.E. & Marshall, F.E. Astrophys. J. 281, 349; 1984). The other black-hole candidates such as Cygnus X-1 switch between 'high'- and 'low'-states for about a month every year or so. (A high-state is characterized by a higher luminosity and steeper (softer) X-ray spectrum and a low state by the opposite.) An X-ray nebula around Cygnus X-1 should then appear as a set of rings around the source marking the past few high-

states. Unfortunately, the other blackhole candidates seem to be in low density regions and the He $\scriptstyle\rm II$ nebula more or less undetectable at present. Indeed, it is curious that LMC X-1 is in a high-density region. The formation of the compact object in a binary X-ray source is expected to impart a substantial velocity to the system by momentum conservation. LMC X-1 should then be a long way away from the region of its birth. Perhaps it just happens to be passing through a dense region.

Pakull and Angebault remark that the LMC X-1 He in region is similar to the narrow-line region of a Seyfert galaxy. We can expect more investigations of the narrow-line region of LMC X-1 to explore this similarity as well as more searches around other black-hole candidates and X-ray sources. Such investigations have already revealed a high-excitation emission-line region around another LMC binary, LHG83.

Palaeoanthropology

Human phylogeny revised again

from Eric Delson

A newly recovered cranium of one of the early human species called robust australopithecines may well force palaeoanthropologists to reconsider the evolutionary relationships among all Australopithecus forms. On page 517 of this issue', Walker and colleagues describe two specimens (a partial lower jaw and a skull lacking most of the teeth and part of the skull roof) found in sediments on the west side of Lake Turkana, Kenya, dated about 2.5 million years (Myr) old. Many of those who have had the opportunity to study a replica of the skull feel that it is the most exciting fossil hominid found since 'Lucy' in 1974 (ref. 2).

The record of early humans (upright bipeds with small canines and apparently already partly expanded brains in comparison to body size) begins about 4-5 Myr ago in eastern Africa. The first wellpreserved remains are those from Laetoli about 3.7 Myr) and Hadar (3.3–3.0 Myr) generally termed A. afarensis. This species is often thought to be close to the base of the radiation of Plio-Pleistocene humans, but opinions differ widely on details. Later australopithecine species include the 'gracile' A. africanus of South Africa, 3.0-2.3 Myr in age; 'robust' A. robustus (and perhaps a distinct A. crassidens) from 1.9-1.6-Myr-old caves in South Africa; and the hyper-robust A. boisei from eastern Africa, well known between about 2 and 1.3 Myr ago. Based on his identification of isolated teeth and the revision of Omo chronology by Brown et al.³, Grine⁴ has argued that A. boisei may occur as early as 2.5 Myr ago in Lake Turkana basin. The earliest Homo fossils appear about 2 Myr ago in both eastern and southern Africa.

Although there is no consensus, most probably agree with the interpretation of Rak⁵ and of Kimbel and colleagues⁶ that A. afarensis is close to the common ancestor of two main lineages of early humans, one leading to Homo but unknown in the 2–3 Myr interval, the other passing through a 'gracile' stage to terminate in several robust species (of which the South African form is most like the common ancestor).

Others, especially Olson⁷, have suggested that A. afarensis is a mixture of two species, with most of the cranial and dental material being an early robust form based on shared features that are considered derived for the robust lineage, whereas Lucy and other less complete remains are like gracile forms and later Homo. Skelton et al. conclude that a third option is best: deriving both Homo and robust forms from A. africanus, with A. afarensis as an earlier ancestral stage.

The new robust fossils add to this already confusing picture. Walker *et al.*¹ make two main points in their analysis.

Age (Myr)

Possible evolutionary relationships among Plio-Pleistocene homínids. Solid lines, known ranges of taxa; dashed lines, probable range extensions and hypothesized relationships.

They argue first, that the new specimens can be included within the known species A. boisei; and second, that their antiquity now makes it impossible for South African A. robustus to have been ancestral to A.

In their Table 2, Walker et al. summarize the distribution among australopithecine taxa of 22 craniodental character states but their data do not, in my opinion, support allocation of KNM-WT 17000 to A. boisei. Of the 22 features, the new skull is apparently phylogenetically conservative in 11 and reasonably conservative in two more; in one (orbital height), it is similarly conservative in that only A. boisei is derived. In having the I² roots medial to the nasal margin, all postafarensis forms are linked indeterminately. Thus, 15 of 22 features are phylogenetically neutral. In four characters, WT 17000 is grouped squarely with the other robust forms by derived features, but then only three remain to place the skull within the robust group. Of these, the shape of the orbital margins links it to A. robustus, whereas foramen magnum shape is shared with A. boisei; in neither character, however, is the state known in A. afarensis nor can an ancestral condition be readily determined.

The absence of a maxillary fossula appears to be a second link to A. boisei, but only if Rak's interpretation of development of the fossula in the africanusrobustus lineage and loss by boisei is accepted. If the fossula and related anterior pillars are functionally linked to canine root size, the fossula could even be independently derived in the two South African species — I consider this character as yet of indeterminate polarity. Walker et al. add to these tabulated features the supposedly boisei-like nature of the infraorbital, nasal and zygomatic root regioins, but interpretations of those similarities differ among observers. We are thus left with only large overall size (and geography) as reasons for including WT 17000 within A. boisei and in the light of the quite distinctive mosaic of characters seen in WT 17000 (for example, prognathic lower face and lack of a bare area where the muscle crests join), I would have assigned it to A. boisei only hesitantly at best. Further analysis (including study of Olson's characters of the mastoid and nasal region) could well show WT 17000 to be a rare case in which a new hominid merits description as a new species.

On the question of phylogeny, Walker et al. have argued that the great age of the new material falsifies the hypothesis that A. robustus or a similar taxon was ancestral to A. boisei. But it is possible (although undemonstrated) that a form resembling A. robustus inhabited southern (or eastern) Africa between 3 and 2.5 Myr ago, giving rise to all of the post-2.5 Myr robust species including WT 17000. As the new skull (and Lucy before it) showed, predicting fossil morphology in barren time periods is a risky pursuit.

But it is morphology and not time that reveals which taxa (or samples) are most closely related, and in this case, it seems best to interpret the new West Turkana robust forms as representing a population near the divergence of the southern and eastern variants. Although retaining

many character states seen in A. afarensis (and perhaps A. africanus as well), the form represented by WT 17000 presents several features characterizing all robust forms but few specific to either boises or robustus. Its discovery leads paleoanthropologists to reassess the trends suggested by Rak for relating the gracile and robust species and the relationship of A. afarensis to all later species. The figure illustrates one such view.

Protein structure

Kinky variations of collagen

from John Galloway

DISCONTINUITIES compel our attention. They are a surprise, as much in the molecular biology of structural tissues as in everyday living. The principle of simplicity leads us to presume that a structure like the triple-helical collagen molecule, with its great uniformity of amino-acid sequence, will also be uniformly stiff and therefore straight or smoothly curving. Intuitively we do not expect it to kink abruptly. Perhaps that is why more than ten years have elapsed before a molecular model first aired in Nature in 1974 and elaborated two years later1.2 has now resurfaced3. In the intervening period the significance of the model has been considerably enhanced. Its interesting and novel feature - then only tentatively suggested1.2 but now formulated more concretely — namely that collagen molecules bend sharply at well-specified positions, now appears (or is thought to appear) in various tissues.

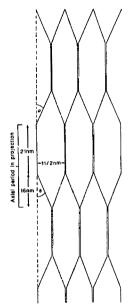

The collagen in question is that of the egg case of the dogfish Scyliorhinus caniculus. It differs from most known structural collagens in that it is secreted by epithelial cells rather than being produced by fibroblasts — a feature it shares, possibly significantly, with the better-known type IV collagen of basement membranes. It also differs from other, better-known, fibrillar collagens in forming a structure with an

axial period of 37 nm rather than the customary 67 nm. Under the electron microscope in transverse section it is seen to possess small crystalline regions in which a square lattice of side 11 nm is apparent. This is another unusual feature. as this sort of direct information has not been available for other collagens.

Briefly, the model (which is still schematic) is as suggested in the figure. The molecules (or groups of molecules) run parallel to the fibre axis along the edges of square prisms of side 11 nm and height 21 nm; they then bend more or less sharply through an angle of about 26° in a plane diagonally bisecting the prism: then run for another 16 nm; and then bend back and resume their course, again along the edges of square prisms but now displaced by exactly half the diagonal of the prism. that is, by $11/\sqrt{2}$ nm. This process continues for considerable distances. In this intriguing model, the simple relationship between successive prisms presumably results from segments of precisely the same length tilting alternatively 'right' and 'left'.

The lattice is, of course, extremely open. The side-to-side separation of the roughly close-packed collagen molecules in rat-tail tendon is about 1.5 nm. in marked contrast to the 11-nm separation seen in the egg-case collagen. Such an

open-work structure presumably provides an extended scaffolding or mesh which is then filled by the extra accessory proteins. It is difficult to avoid the conclusion that the large molecular tilt is the mechanism by which the open-work threedimensional mesh is rendered possible at all, and kept mechanically stable. It is worth remembering that regular, planehexagonal meshes of collagen molecules have been proposed as a feature of basement membranes4. This may turn out to be a particularly useful comparison if, as is now speculated', the egg-case colla-

Presumed arrangement of collagen molecules in planes diagonally bisecting the 11-nm square prisms, a molecular arrangement similar to the Z disks of striated muscle. $\theta = \tan^{-1}(11/16\sqrt{2}) \approx 26^{\circ}$.

gen is closely related to that of the basement membrane.

There remains the question of what features of amino-acid sequence cause the molecule to bend. Because little or nothing is known of the sequence of eggcase collagen, the question cannot be addressed directly, but it might be worth rehearsing some options borrowed from other, better-described collagens. Again because of the possible link, basement membrane collagen might offer a clue. Hoffmann et al. report' that the flexibility of the type IV molecule varies in a marked way along its length and claim this to be consistent with what is known of the amino-acid sequence of the molecule, namely that it contains several interruptions in the otherwise regular sequence of triplets, Gly-X-Y. This approach has led to a view of the molecule as a series of stiff, triple-helical segments connected by short lengths of flexible non-helix.

A similar mechanism certainly seems to operate in the best-described collagen kink — that found in the molecule C1q of the complement system. All three chains, A, B and C, of the triple-helical parts of

the molecule have been fully characterized. Close to the kink in A, threonine is inserted between two triplets; an alanine substitutes for a triplet glycine in C and an entire extra triplet is apparently inserted into B (ref.6).

On the face of it this interruptive mechanism would not be generally available to vertebrate fibrillar collagens where the amino-acid sequence within the triplehelical part of the molecule seems to be encoded exclusively by exons containing an integral multiple of 9m nucleotides (m = 5.6.11.12 and 18) so that each exon encodes an integral number of triplets (unless the interrupting part itself always consists of triplets). Invertebrate collagens are less constrained. Could bending be brought about by mechanisms not involving residues actually interrupting the triplet sequence? For example, some regions of the molecule might simply be less thermodynamically stable. Hoffman et al.5 suggest that because imino residues are usually thought to confer stability, their absence over short regions might reduce local stiffness.

It is perhaps worth considering another possible mechanism in this class. The most striking single feature of the sequence of 1,014 residues in the triple-helical part of the a_1 (I) chain is the presence of a solitary, idiosyncratically placed glycine. The sequence contains 1,014/3 = 338glycines, each in position 1 of the triplet, and one glycine, residue 311, in position 2. Such a small residue in place of a much bulkier one could well promote buckling, especially as the extra glycine is a feature of two out of the three chains (the $\alpha_2(I)$ chain does not have it).

At least two detailed models for the structure of rat-tail tendon invoke molecular kinking^{7,8} and both suggest possible kinking sites at the gap/overlap interfaces.

The 67-nm D-period, which includes one gap and one overlap region, is known to run through almost 234 residues and the whole triple helix runs through 4 gaps and 5 overlaps. Thus the overlap length is $1,014 - (4 \times 234) = 78 (D/3)$ residues. The position of the interfaces are given by 234n, where n = 0.1.2.3.4 and 234n + 78. When n = 1 the interface falls at residue 312, that is, within one residue of the additional glycine.

Without a lot more work this observation, although interesting, is obviously no more than that. If every molecule kinks at every interface, what mechanism is operating at the other seven potential kinking sites? Perhaps the molecule does not kink at every potential site. At least one other case of a double glycine within a triple helix, residue 73 of the B chain of Clq, is not associated with kinking9.

If kinking is an important and universal feature of collagens then the range of ways in which it is contrived are worth studying, as are the ways in which genes conserve such crucial structural features. Reid9 has pointed out that in the gene encoding the B chain of C1q the single intron is located inside the codon for the glycine (other examples are known) within the inserted triplet and speculates that it might play a part in conserving the kink as a functionally important feature.

Muscle contraction

Through thick and thin

from Peter D. Chantler

Two recent papers report observations that both confirm and extend our ideas about how muscle contraction is regulated. Knox et al. look at the role of tropomyosin in regulatory myosins, whereas Bennett and Bagshaw² investigate the non-specific divalent cation binding site of myosin, the major protein of the thick filament.

Regulation of muscle contraction can be divided broadly into two types: thin filament control and thick filament control. Thin filament control, typified by vertebrate skeletal muscle, is a function of actin, tropomyosin and troponin. During activation of muscle from the relaxed state, troponin senses the calcium signal,

causes tropomyosin to move in the groove of the actin helix and thereby removes the obstacle that prevented attachment of myosin heads (crossbridges) to actin this is the well-known steric blocking model (Fig. 1a-c). In thick filament control, exemplified by scallop myosin, regulation of actin-myosin interactions is controlled by conformational events on the myosin head subsequent to calcium binding at a specific site (Fig.2, site 2). Hence, there is no need for tropomyosin movement in this form of regulation: indeed, full regulatory behaviour is observed in the absence of tropomyosin.

A practical consequence of the steric blocking model, reported many years

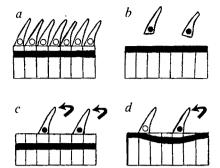

Fig. 1. The simplest explanation of rigor complex formation operative in thin filament regulation. Actin is represented as a set of 7 subunits; myosin heads can interact with only one subunit at once. Open circles, no bound ATP; closed circles, bound ATP; solid band, tropomyosin. Magnesium (>10 3 M) is present in all cases. a, Rigor. No ATP; myosin heads bind to actin as a tight complex, pushing tropomyosin out of the way. b, Relaxed situation. ATP $> 10^{-3}$ M, Ca²⁺ $< 10^{-7}$ M; myosin heads are prevented from binding to actin by tropomyosin assuming a blocking position. c, Active situation. ATP > 10^{-3} M, Ca^{2+} > 10⁻⁶ M; myosin heads attach to, then detach from, actin in a cyclic, force-generating manner; tropomyosin is displaced to a non-blocking position. d, Rigor complex formation Ratio of ATP to myosin heads < 1.0, Ca²⁺ < 10⁻⁷ M; rigor attachment of myosin heads, without bound ATP, pushes tropomyosin out of the way, thereby allowing heads possessing ATP to elicit force generation.

ago', was the ability of crossbridges to cycle in the absence of calcium and at low concentrations (less than 50 micromolar) of ATP. These observations were interpreted as follows: at low levels of ATP (no calcium, 1 millimolar magnesium) a finite population of nucleotide-free myosin heads exist. These form 'rigor' complexes with actin, in the process pushing tropomyosin away from its blocking position such that active myosin heads, possessing nucleotide, now have access to actin and can turn over (Fig. 1d). Similar results were not observed with scallop preparations³, a finding that has not been reported in full until now1

Because scallop adductor muscle is thought to be regulated solely by myosinlinked regulation, one would predict that there is no cycling of crossbridges in the absence of calcium at low levels of ATP, as such an effect seems to be a consequence of thin filament control. Nevertheless, several irksome observations have been made over the years: the X-ray diffraction patterns from contracting, rigor and relaxed molluscan muscle, interpreted as a movement of tropomyosin in the actin groove⁴; the presence of troponin subunits in some molluscan muscles⁵; and the apparent demonstration of a reversal of actomyosin relaxation at low ATP levels (by turbimetric assay) in both scallop and squid muscle⁶. Knox et al. principally address this latter point.

These authors examine the effect of low ATP concentrations on the relaxation of scallop myofibrils by ATPase, turbimetric and light-microscope techniques. Using ATPase, they observe no increase in activity at low ATP concentrations in the absence of calcium, which leads directly to the conclusion that no crossbridge cycling is allowed in regulated scallop myofibrils at reduced ATP levels, exactly as predicted for a myosin-linked system.

Curiously, the turbidity measurements of Knox et al. confirm earlier observations6 that reported an increase in optical density at reduced ATP concentrations, both in the presence and absence of calcium. These results appear to point to the exact opposite conclusion — that cycling is allowed at low ATP levels. This apparent contradiction was resolved by light microscopy: comparison with myofibrillar shortening indicates that turbidity cannot be equated with contraction, but instead appears to be associated with shrinking and swelling of the myofibrils'. Speculation that all forms of myosinlinked regulation will produce results similar to those obtained with scallop by Knox et al. should be tempered by the knowledge that tropomyosin can influence actin-activated ATPase rates in myosins controlled by light-chain phosphorylation.

Bennett and Bagshaw, on the other hand, examine the rate of release of divalent cations from myosin subfragments (proteolytic portions of the molecule), in particular, from the high-affinity, non-specific sites known to be localized on the regulatory light chains of all myosins (Fig. 2, site 1). Several years ago, Bagshaw and Reed' reported that the rate of dissociation of magnesium ions from this site on rabbit myosin subfragments was too slow to account for the rate of onset of contraction (complete within 100 milliseconds). They reached this conclusion by observing the decay of protein fluorescence consequent on chelation of the metal ion by EDTA in a stopped-flow apparatus. One criticism of this work is that measurement of the fluorescence signal was indirect and may have monitored a slower change on the protein that is subsequent to cation dissociation.

Bennett and Bagshaw⁶ have now repeated the measurements, this time monitoring events at the metal-binding site (Fig.2, site 1), and have extended them to include scallop myosin subfragments. They have taken advantage of a neat spectroscopic trick to overcome the problem that Mg2+ is spectroscopically transparent under the conditions required to monitor its binding to protein. The trick is that manganese ions (Mn2+) are not invisible by electron paramagnetic resonance and will give a tell-tale spectrum which becomes broadened when Mn2+ binds to the divalent cation site on the regulatory light chain, for which it competes effectively with Mg. Thus, by displacing bound Mg2, it was possible to monitor the decrease in signal of unbound Mn²⁺, thereby obtaining Mg²⁺ dissociation rate constants from both rabbit and scallop subfragments that are similar to the earlier measurements obtained by protein fluorescence (0.05-0.06 per second). Magnesium is therefore lost from these sites at a rate that is too slow for the ion to be replaced by activating concentrations of calcium (though one cannot exclude the possibility that some calcium is bound to the sites during a prolonged tetanus).

This result is no surprise to thick filament afficianados who have known for some time that these two high-affinity. non-specific sites exist in addition to the two calcium-specific sites (Fig. 2, site 2) located on scallop myosin, and it is this latter pair of sites that is responsible for the activation of contraction in scallop muscle. But for rabbit myosin there are no

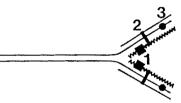

Fig. 2 Metal binding sites on myosin Site 1 is the Ca/Mg site, located on the regulatory light chain; site 2 is the calcium-specific control site, found on scallop myosin (its exact location is unknown but it requires ligands from both the regulatory light chain and the myosin heavy chain), site 3 is the active site on the myosin heavy chain where ATP binds (usually in association with a divalent cation).

alternative sites: if one excludes the highaffinity regulatory light-chain sites as calcium switches, as the work of Bagshaw and colleagues appears to have done, then one must conclude that no on/off divalent cation switch exists on the thick filament of rabbit skeletal muscle, a result in harmony with many earlier observations Although the activity of the ATPase site on rabbit myosin is undoubtedly influenced by the presence or absence of bound calcium and regulatory light chain. this influence is modulatory in nature, the true calcium switch being on the thin filament. The nature and location of the calcium-specific sites on scallop mysom is still unknown.

Fluid mechanics

G.I. Taylor and his influence

from Herbert E. Huppert

SIR Geoffrey Ingram Taylor OM, FRS was one of the giants of physical science in this century. His work was at the centre of research on the mechanics of fluids and solids and their application to aeronautics, chemical engineering, meteorology, mechanical engineering, metal physics and oceanography. He had a distinctive style of research that brought penetrating insight into the fundamental nature of almost all the problems he considered. At the same time, he was generally able to

Sir Geoffrey Taylor investigating the motion of a fluid in a partially filled spinning cylinder. design simple but effective laboratory experiments that tested, and usually confirmed, his theoretical concepts. Taylor was born on 7 March 1886 and, at a recent meeting* to celebrate the centenary of his birth, it was asked whether the style of his work is still alive, and of value, to contemporary research workers.

Taylor liked to describe himself as an amateur scientist — by which he meant that he enjoyed working independently, with a minimum of help from others, and, of central importance, for pleasure. His scientific curiosity led him frequently to initiate new areas of research, only to lose interest in them after he had discovered the fundamental phenomena of one field, by which time the possibility of developing another novel field struck his imagination. After the tragic sinking of the Titanic in 1912, Taylor was invited to be the meteorologist on the old sailing ship Scotia, which had been requisitioned to investigate the motion of icebergs in the North Atlantic. While on board, he grasped the opportunity to design instruments attached to balloons and kites flown to heights of 2 km from the masthead of the ship. From these instruments, Taylor obtained the first reliable estimates of the transfer rates of momentum, heat and water vapour in the lower atmosphere. This work consolidated his interest in meteorology and turbulent diffusion and dispersion, to which he contributed so much in later years.

Taylor also originated important ideas in solid mechanics. A series of definitive experiments on various materials led him to develop a theory for 'dislocations' in metal crystals which predicted how cracks propagate and accounted for the observed strength of metal crystals. Motivated by conversations with Lord Rothschild, Taylor initiated the quantitative study of the swimming of microorganisms and, on the way, constructed a model of the tail of a spermatozoon from a metal-wire helix enclosed in a rubber sheath. The sheath rotated by the action of a wound-up rubber band anchored inside a head at one end of the helix. This model swam through glycerine at a rate that agreed with Taylor's theoretical prediction.

Because of the wide-ranging applicability of fluid and solid mechanics, and because of Taylor's ingenuity, his abilities were called on during the two world wars. In 1914 he helped to investigate the design and operation of military airplanes. While doing so he learnt to fly and make parachute jumps; operating as both experimenter and pilot he made the first pressure measurements over a wing in steady flight. During World War II he analysed and advised on a wide range of problems, including the rate of propagation of blast waves emanating from intense explosions.

Taylor produced more than 200 scientific papers spanning the years from 1909 to 1972. An example of his inventiveness occurs in his design of an anchor. Unhappy with the holding power and weight of the traditional anchor, Taylor created a totally new design, with a single hook shaped like a double-bladed, symmetrical plough-share. This was much lighter than traditional anchors yet had the same holding power. These 'CQR' anchors are now widely used in small vessels and are still the best available.

Is it still possible, and useful, to carry out current research in the style of G.I. Taylor? He used his intuition and just sufficient mathematics and experimentation to develop extraordinary insight into the general nature of the area being considered. As was clear from the recent meeting, this style, although not easy to \square imitate, is currently being used to good effect in several areas of fluid mechanics. The conference confirmed that current research in fluid mechanics, in contrast to some other subjects, permits important contributions to be made on a very broad range of problems. These include dynamical problems such as chaotic and turbulent behaviour in the atmosphere and oceans and in industrial contexts. Another important area concerns the formation of finger' patterns when fluid of one viscosity displaces fluid of another within a confined space — a subject also started by Taylor, who wanted to understand how oil could be recovered from porous rock by driving it up ahead of a heavier, less viscous water layer pumped into the base of the rock. Such questions continue to demand all the imagination and ingenuity of Taylor's successors and will be solved by individual scientists or small groups working on their own — and for pleasure.

Catalysis

Designing porous solids

from John M. Thomas

A JET of hydrogen impinging in air on platinized, fibrous asbestos produces a spark. The famous nineteenth century German chemist, Döbereiner, capitalized on this phenomenon in the first commercial exploitation of heterogeneous catalysis. More than a million tinder boxes, containing compartments housing zinc and acid to generate the hydrogen, were made in the late 1820s and used as fire-lighting devices. The key to their operation is the degree of subdivision of the platinum engendered by the exceptionally large area of the fibrous support: no sparks are pro-

duced with platinum wires, rods or foils of low area. Chemists ever since have been seeking new large-area solids, especially those that function as synergistic catalysts with a supported metal — such as rhodium for the control of automobile emissions, or palladium for the production of many pharmaceuticals. But industrial catalysis is not the only driving force in this quest. Porous solids are also required as platforms for a range of immobilized enzymes, as improved columns in adsorption and ion-exchange chromatography, and for effecting gas separations such as meth-

^{*}Fluid Mechanics in the Spirit of G.I. Taylor, University of Cambridge, 24-28 March 1986.

clones derived from these tumours which either lack or have a relative deficiency of H–2K antigens tend to grow and metastasize more readily than similar cells transfected with and expressing an H–2K gene but that were originally H–2K deficient. Evidence was presented to suggest that surveillance by T lymphocytes is the most likely relevant anti-tumour host response in these experiments in that T cells recognize tumour-associated antigens only when associated with certain class I antigens (MHC restriction).

An apparently contradictory result is found (K. Kärre, Stockholm) in YAC -I tumour cells induced by Moloney virus where increased amounts of H-2 antigen expression is directly related to increased metastatic potential. But the host response in this case is apparently related to natural killer cell activity, which operates best in the absence of H-2 antigens on the target cells.

T-cell surveillence may be relevant however, as when large doses of these tumour cells are injected into preimmunized animals their growth is favoured by the absence of H-2 antigens. In individual primary AKR lymphomas the quantitative expression of H-2K and H-2D antigens correlates with the quantity of a murine leukaemia virus-encoded glycoprotein on the cell surface (P. Demant, Amsterdam). This could ensure the preferential elimination by cytotoxic T lymphocytes of cells with high levels of expression of viral antigens.

Although T-cell surveillance is clearly dependent on the presence of the relevant class I MHC molecule in most instances, there are exceptions in some AKR leukaemias (W. Schmidt, Essen) and in some human Burkitt lymphomas (E. Klein, Stockholm) which are resistant to T-cell cytoxicity even though the relevant restriction elements are apparently present. These findings stress the importance of the heterogeneity of the quality and quantity of the host's immune responses to tumours.

As the level of expression of H-2 antigens on syngeneic tumour cells is relevant for host-tumour interactions, it is important to elucidate the mechanisms of control. Three presentations were in agreement in proposing that DNA methylation is likely to be as important in regulating expression of both class I and II MHC antigens and also the Thy 1 antigen. C. David (Rochester) showed that Class II H-2 antigens are expressed after treating the BW 5147 thymoma line, with the demethylating agent 5-azacytidine; E.

Erratum

In the article by K.A. Browning et al. on atmospheric fronts (*Nature* 322, 114; 1986), Fig. 2 should have been rotated clockwise by 90 degrees to relate to the model simulation shown in Fig. 1.

Pareja (Granada) showed a similar result for class I antigens after treating an H-2-negative GR9 tumour cell clone with 5-azacytidine. He also showed differing methylation patterns that correspond to the different levels of expression of H-2 antigens on the various tumour cell clones

F. Grosveld (London) came closer to identifying a site of action by showing that the methylation of the 5' flanking region of the Thy 1 gene is responsible for the control of expression of this antigen. Possible transcriptional and post-transcriptional mechanisms mediated by transforming proteins of DNA tumour viruses that may also account for the regulation of class I antigen expression in SV40-transformed cells were indicated by P. Rigby (London). Ultimately these studies will open the way for the manipulation of host-tumour interactions through the regulation of syngeneic H-2 antigen expression.

Expression of aberrant H–2-like alloantigens by tumour cells was originally described about 10 years ago by the group of one of us (H.F.), soon followed by similar observations of others. There is new molecular evidence for the expression of an H–2D^d-like specificity on an H–2K AKR leukaemia (H.F.) and Schmidt described an aberrant H–2K¹-like molecule which is responsible for rejection of a tumour induced by the Rous sarcoma virus that does not express normal syngeneic Class I antigens.

H. Schreiber (Chicago), M. MacMillan (Los Angeles) and R. Goodenow (Berkeley) discussed the well-characterized novel class I MHC molecules identified on the ultraviolet radiation-induced fibrosarcoma 1591. What is of interest here is that the genes encoding two of these molecules have a high degree of homology with H-2L which is not normally expressed on cells of the H-2^k haplotype.

Thus chemicals or viruses may induce gene rearrangements that cause derepression of silent genes, leading to the appearance of aberrant H-2-like allogeneic molecules. The multiple Qa- and Tla-like genes that have a considerable degree of homology with H-2 genes could provide the genetic basis of aberrant MHC antigen expression. Such H-2-like molecules capable of eliciting an immune response may function as tumour-associated transplantation antigens, or be intrinsically suppressive in another genetic context. P. Demant (Amsterdam) and P. Stern (Liverpool) both showed class I-like products on embryonal carcinoma cells but disagreed on whether they were normal or aberrant products.

Expression of MHC antigens on human tumour cells was also considered. 'Extra' HLA class I-like specificities of the AW19 cross-reactive group on HTLV-I infected cells were described by D. Mann (NIH)

and were attributed to the high degree of cross-reactivity between virally induced tumour-associated antigens and these HLA specificities. P. Schrier and D. Ruiter (Leiden) and F. Ruiz-Cabello (Granada) both found a lower level of expression of class I HLA antigens in metastatic compared with primary melanomas but G. Parmiani (Milan) tound no difference between the level of class I MHC antigens in metastatic and primary melanomas.

Difficulties are encountered in interpreting the results of some of the other solid tissue human tumours studied. where extreme heterogeneity of MHC antigen expression in individual cells within the tumours is found. This is true for several solid tissue tumours, including breast carcinomas (J. Peña, Cordoba and M. Perez, Granada) and gastrointestinal neoplasia (M. Moore, Manchester). In a study of colorectal carcinomas Hammerling and Peña find a correlation between the loss of MHC class I antigen expression and the degree of cell dedifferentiation within the tumours. We believe that both these solid tumours and chemically induced tumours in mice arise from multiple clones having differing levels of expression of MHC antigens. Class II MHC antigen levels could thus be indicators for metastasizing melanomas (Ruiter: Parmiani).

C. Navarrete (London) reported difterential expression and function of MHC class II antigens (DR, DQ) on various acute leukaemic cells and cell lines. These findings may have important biological consequences in host-tumour interactions as was implied further by the data presented by A. van Leeuwen (Leiden) on the expression of TCA- (Tla-like) antigens on several human leukaemias.

Another question concerns the association of MHC antigens with particular tumours. M. Zijlstra (Amsterdam) demonstrated in mice that alleles of class II *I*–*A* control the type of lymphoma that develops (T,B or non T, non B) with MCF 1233 virus. T. Oliver (London) showed, significant positive association between HLA-DR5 antigen frequency and the development of seminomas in man.

It appears the genetic basis for the expression of aberrant MHC antigen specificities on tumour cells is probably the result of a series of gene-conversion events and DNA rearrangements involving pseudogenes and genes encoding differentiation antigens and by various initiating factors including toxic chemicals, radiation effects and viruses and influenced by host lymphokines.

The origin of Japanese HTLV-Ī

SIR-Gallo and his colleagues' seem still to believe that African blacks came to Japan with the Portuguese in the sixteenth century, that HTLV-I (human T-lymphotropic virus type 1) adult T-cell leukaemia virus was transmitted from them to the Japanese people and then became highly endemic in Japan². But our studies^{4,5} strongly suggest that HTLV-I was already present in aboriginal Japanese in prehistoric times.

There are at least three ethnically distinguishable populations in Japan: the Ainu in the north the Ryukyuans in the south and the Wajin, or "Japanese", inhabiting the rest of the country. In our examination of the prevalance of HTLV-I in these ethnic populations46, we found that the incidence of virus carriers was highest in the Ainu and the Ryukyuans, not the Wajin, and that the seroprevalent frequencies in adults over 40 years old of these three ethnic groups were 45.2%, 33.9% and 1.1% respectively,4.

The Wajin, who constitute most of the present population of Japan, are considered to be descendents mainly of post-neolithic immigrants from the mainland in the Yayoi and the Kofun eras (300 BC to AD 600). The Ainu and Ryukyuans, who share several common physical and genetic traits, are considered to be relatively pure descendents of native Japanese populations. The Ainu in particular are regarded as descendents of the native population inhabiting mainly northern Japan from the pre-agricultural Jomon period, more than 2,300 years ago.

The highly endemic areas of the retrovirus in Japan have been demonstrated to be restricted to (1) the most northerly and southerly regions and (2) isolated areas in other regions^{5,7,8}. These native populations have been relatively unaffected by the Wajin, who are not HTLV-I carriers. In most other areas, however, the Wajin became predominant because of their higher technological skills, planting rice and making iron tools and arms, for example.

Gallo and his colleagues' state that "the Japanese word for monkey amakawa is... derived from the Portuguese word macaco, also meaning monkey, however, we do not call monkeys amakawa, but saru. Furthermore the Japanese word amakawa is derived from Macao, the Portuguese territory in China. It may be true that the Portuguese brought Africans and African monkeys to Japan, but there is no relation between the places where the Portuguese landed in Japan and the endemic area of HTLV-I9.10. Among the Ainu people living in Hokkaido (the most northerly island of Japan) there are no monkeys living outside zoos, HTLV-I is prevalent, but Roman Catholicism, which Gallo et al. say was imported from Portugal, is not. Thus, the hypothesis that Japanese HTLV-I derives from Africans brought by the Portuguese in the sixteenth century is inadequate. Alternatively, from our recent finding that HTLV-I is prevalent in northern Japan and the report of Gallo's group of the presence of HTLV-I carriers in the Arctic", we propose that, like simian HTLV-like virus, which is now found in Old World monkeys12 14, HTLV-I was originally prevalent in all humans, but that during human evolution it was lost from all but a few populations.

Finally, we think that it is premature to draw a conclusion on the origins of HTLV-I, because many populations have not yet been examined.

Phosphoinositol more than skin deep

SIR—Touqui et al. may have been too cautious in the discussion of their paper which showed that the phosphoinositol (PI) cycle is responsible for activation of phospholipase A, (PLA,) and initiation of the arachidonic acid cascade in platelets'. Our current studies of epithelial growth control provide data that are in line with their hypothesis, allowing us to interpret the findings of the Paris group in a broader context. It has long been recognized that a tissue responds to injury in two ways inflammation and regeneration - and that these are tightly coupled; indeed, in normal circumstances they are inseparable. From a teleological point of view this of course makes sense, but in mechanistic terms still awaits an explanation. We are now in a position to provide one, namely that both arms of the response are triggered by activation of the PI cycle.

As in certain other tissues, PLA, activity in human epidermis is calcium-dependent and appears to be inhibited by a lipocortin-like molecule': the epidermal inhibitor also seems to be modulated by phosphorylation3. Thus the findings of Touqui et al. may be extended to epidermis, a conclusion strengthened by the report that phorbol myristic acetate increases the synthesis of arachidonic acid metabolites by cultured keratinocytes. These metabolites include prostaglandins (responsible for vasodilation) and chemotactic agents, such as leukotriene B, which initiate invasion of the tissue by granulocytes.

The link with proliferation was originally suggested by observations that protein kinase C, following activation by diacylglycerol, phosphorylates (and hence activates) a membrane antiport which exchanges intracellular H+ for extracellular Na*. In several cell types the resulting increase in cytosolic pH causes entry of resting (G₀) cells into the mitotic cycle^[5,6]. Again, extrapolation to epithelia seems reasonable, since phorbol esters applied topically to skin cause a dramatic hyperproliferation.

Further evidence comes from our unpublished observation that inhibitors of the antiport and/or protein kinase C, such as amiloride, abolish the recruitment of G_n keratinocytes in human epidermis following experimental injury.

Thus the findings of Touqui et al. may well lead to a clearer understanding of the way in which a tissue responds to injury, one of the central problems in pathology. We would also note its relevance to psoriasis, a common skin disease with polygenic inheritance. The lesions of this disease are characterized by a continuous, chronic inflammation and secrete high levels of arachidonic acid metabolites7. The epidermis within the lesions is grossly hyperproliferative with a complete absence of G, cells' and PLA, activity increases in the entire epidermis of the patient which seems to result from an over-phosphorylation of the inhibitor3. It would seem that the PI cycle may be a rewarding field for research into the pathogenesis of this disease.

Faith in the physicists

Joseph Silk

In Search of the Big Bang: Quantum Physics and Cosmology. By John Gribbin. Bantam/Heinemann: 1986. Pp. 413. Pbk \$9.95, Hbk £14.95.

SUSY GUTS is not a radical feminist, but a theory that is designed to unify the fundamental forces of nature. The reader will find this, along with many other esoteric facts, relieved by occasional gossipy anecdotes, in the latest book from prolific science writer John Gribbin.

In Search of the Big Bang completes a trilogy of major works on what Gribbin considers to be the most important scientific achievements of the twentieth century. Previous volumes were devoted to the nature of reality and quantum physics, and to the origin of life: here we move onto the ultimate issue of the creation of the Universe itself. The faint of heart may dispute the status of our cosmic origins as an equal partner to these other matters, but Gribbin unabashedly takes us on a grand tour of modern cosmology.

The difficulty is that cosmology is a science starved of data and not readily amenable to controlled experiments. We must take each glimpse of the Universe as it comes, no matter how confused or obscure it happens to be. Remote galaxies appear as they were acons ago, and thereby profoundly alter our normal sense of perspective if, for example, young galaxies were more luminous than the mature, nearby galaxies. It is as though we view the Universe through a distorting lens, and we have little sense of the nature of the distortion. And this applies to the galaxies, whose formation was only the most recent episode in the history of the Big Bang. Extrapolating backwards in time from the furiously receding galaxies we see today, we infer that the Universe was once a far more exotic, denser, hotter hostile place.

In many respects, the Big Bang is to modern cosmology what mythology was

to the ancients. To believe that we understand the very early Universe, the first microseconds of cosmic time, requires immense faith in the physicist's search for the ultimate union of the fundamental forces of nature, because direct evidence is completely lacking. Yet to the physicist, the vast energies attained in the immensely compressed primeval fireball that was once the Universe offer a unique testing ground for the latest theories of elementary particles. Exotic names, like photinos, strings or even superstrings, are reeled off as though they were the most natural state of matter, which perhaps they once were. Provided we accept theories of matter and gravity that are certainly correct at our present epoch and in our environment, then we are inevitably led by the Big Bang to a singular state near the origin of time.

Of course we are still awaiting the ultimate theory of everything, currently thought to be superstrings, which will explain the most important missing link in the puzzle, namely how it all began. Many physicists around the world are pursuing this ultimate goal that represents the union of gravity and quantum mechanics. However, we are not there yet, and opinions differ widely as to how far away we may be: according to Stephen Hawking, the end of physics is in sight, yet Sheldon Glashow argues that superstrings are only a mirage.

My only quibble with Gribbin's book is that he presents physicists and astronomers as gods whereas, in reality, they are no less fallible than other mortals. The Big Bang theory is an excellent description of the here and now, and of the not-so-longago and not-so-far-away. But one ought to take the extrapolations back to the begin-

ning of time with a healthy dose of scepticism. The Big Bang cosmology may yet be superseded, just as Newton's theory of gravitation was incorporated by Einstein into a new theory. Our more extreme extrapolations of space and time could prove to be equally false, or at least, incomplete.

In Search of the Big Bang is a remarkably readable guide, however, to the mysteries of cosmic creation. It is strong on personalities, from anecdotes about missed opportunities and Nobel prizes, to the story of the wealthy telescope builder and the mule skinner who paved the way to the realm of the nebulae. The first third of the book represents a historical development of cosmological data, and the second third provides a readable description of the classical Big Bang theory. The remainder is devoted to quantum physics and the very early Universe. Rife with speculation and liable to become largely irrelevant overnight, the last third of the book is the weakest section. But it is definitely worth reading, if only to find out how Kaluza, the founder of higher dimensional cosmology, learnt to swim.

Fact or fiction?

C.E.M. Hansel

Science Confronts the Paranormal. Edited by Kendrick Frazier. *Prometheus: 1986 Pp.367. Pbk \$15.95, £12.95.*

SCIENCE Confronts the Paranormal contains a selection of articles published by the Committee for the Scientific Investigation of Claims of the Paranormal in its journal The Skeptical Inquirer. The book is divided into two sections. The first of them, "Assessing Claims of Paranormal Phenomena", is mainly concerned with parapsychology — including poltergeists. and the claims made by mediums and professional "psychics" - together with palmistry and iridology. The second section, "Evaluating Fringe Science", covers unidentified flying objects, fringe archaeology, creationism, the Turin shroud, astrology and the Loch Ness Monster.

The general approach is set out in the introduction and early chapters. Stephen Toulmin suggests that consideration of the manner in which new ideas have been opposed will "induce a certain modesty even about our skeptical doubts". Paul Kurtz also considers that the claims made by "paranormalists" should not be rejected out of hand. But over the history of scientific inquiry it is difficult to identify a new idea that has been rejected for long, provided that observations could be convided.

Jodrell Bank radio telescope nearing completion in April 1957. Taken from Bernard Lovell: A Biography by Dudley Seward, which includes a summary of Lovell's views on the nature and origins of the Universe, Now available in the USA (Salem House, \$21.95). For review, see Nature 312, 210;

The spoon-bending abilities of Uri Geller, a professional magician who claimed to be psychic, made headline news. Scientific tests of his powers have now become "little more than a collection of anecdotes"

firmed adequately or that a new hypothesis could be tested experimentally and confirmed by independent investigators.

Most of the claims examined in the first section are not new, but are dependent on ideas going back into prehistory that have failed to be accepted within science. They have not been totally rejected for scientists from many disciplines working within parapsychology have been attempting to provide repeatable experimental demonstrations of the various psychical phenomena for more than a century. When such a demonstration becomes available, it will then be necessary for the sceptics to see whether they can also confirm its findings. The main reason for examining such claims in advance of evidence supporting them is made clear by Kurtz: "... we are confi cerned not simply with paranormal beliefs in the laboratory but with their dramatization in the media".

Two types of investigation may be distinguished: first, experiments, in which the researcher decides on the experimental design and procedures to be adopted whilst the subject does as he is told; second, demonstrations, in which a person attempts to convince observers of his psychic powers. Here the investigator observes the subject while he performs under his own conditions, often reminiscent of those enjoyed by a conjuror in the music hall.

What has emerged from the experimental work is that attempts to confirm an original "positive" finding will either fail or "succeed" at a low level of significance, the result depending mainly on the experimenter. This has led to the conclusion within parapsychology that there is an "experimenter effect"; which is not dependent on the slap-happy nature of the investigation but on some new interaction between the experimenter and the hypothetical process being considered. Of particular interest here is the discussion of an experiment on "remote viewing" - or clairvoyance - reported in Nature (252, 602; 1974) by Targ and Puthoff of the Stanford Research Institute (SRI). The experiment was shown by Marks and Kamman (Nature 292, 177; 1981) to contain a schoolboy blunder that could account for the result. Marks himself reviews this and further experiments which claimed to indicate that the fault in the procedure made no difference to the result. His conclusion is that:

Well-controlled experiments never find the RV effect, while poorly controlled experiments nearly always do so. Data suppression, flawed methodology, and lack of replication lead to the conclusion that remote viewing is a cognitive illusion, an artefact of human error and wishful thinking.

An investigation of the second type is discussed by Martin Gardner in "How Not to Test a Psychic: The Great SRI Die Mystery". Uri Geller, a professional magician who claimed to be psychic, was tested during a visit to SRI where it was stated that he was able to name correctly the face uppermost on a concealed die on each of eight attempts and that he made no attempt on two occasions. After discussing means whereby any trained conjuror might have obtained similar results, and his attempts to find out more about the tests, Gardner writes:

What conclusion can we reach from all this? The most important is surely the following. What seemed to any reader of *Nature* to be a carefully controlled die test has now become little more than a collection of anecdotes.

The section on fringe science is concerned in the main with certain claims that are not inconsistent with contemporary scientific theory but that are not supported by evidence. A large amount of material is available here relating to matters that become headline news but are seldom reported fully and critically.

Science Confronts the Paranormal should be of considerable value to those puzzled by accounts of "paranormal" events appearing in the media, to teachers interested in the scientific method and to parents who are disturbed by what their children are taught. It could well be made compulsory reading for science correspondents and television producers.

Wide sweep

A.J. Thomson

Physical Methods for Inorganic Biochemistry. By John Wright, Wayne Hendrickson. Shigemasa Osaki and Gordon James. *Plenum: 1986. Pp.384. \$71.40, £47.60.*

The task this book sets itself is ambitious. It attempts to cover the spectroscopic, diffraction and analytical methods used to probe the structural properties of the elements employed by living organisms. But, before beginning, the authors needed to decide whether to write a book about the methodology of the techniques, their principles and practice, or to describe the ways in which our understanding of biological systems has been advanced. This choice has not been made, and as a result most chapters fall short of meeting either goal.

The consequences of indecision are seen clearly in the chapter on the principles, practices and applications of nuclear magnetic resonance (NMR). Here the authors have slipped between three stools. Principles are stated briefly but inadequately, and it is doubtful that those readers who do not understand the basis of Fourier transform NMR, say, will be much clearer after reading this section. The description of practice extends to giving absurd detail for a circuit diagram of a low-pass noise filter — surely a topic for a technical manual — while applications are dealt with on an element-byelement basis; this makes a useful compendium, but hardly shows the powerful ways in which NMR has helped biologists.

To make things worse, the authors have tried to cover too many techniques, several of which are as yet of little established value in biological research. For example, nuclear quadrupole resonance (NQR) spectroscopy is an insensitive technique that has produced no information of biological significance. Electron spectroscopy (ESCA) is also out of place, whereas EXAFS (extended X-ray absorption edge fine structure) is not discussed even though it has had considerable impact. The sweeping scope has inevitably led to areas being tackled that are well outside the authors' competence — the statement that "there have been few temperaturedependent magnetic circular dichroism studies of transition-metal enzymes" is false and renders the chapter concerned out-of-date and inadequate.

Altogether, it is difficult to see the aim or the value of this book. Much of the material is available elsewhere, either in reviews or texts on the individual techniques written by more authoritiative authors.

New frontier for stratigraphy

A.M.C. Şengör

The Geology of China. By Yang Zunyi, Cheng Yuqi and Wang Hongzhen. Oxford University Press: 1986. Pp.303. £55, \$79.

WITH 9.6 million km² China covers nearly one-fifteenth of the world's land area and is the third largest country in the world. The geology of this vast portion of our planet is now being studied by some 70,000 geological personnel in China. Their results are reported regularly in some 50 Chinese periodicals and monograph series, only a few of which contain English abstracts. The Geology of China, the second book of its kind since Li Siguang's (J.S. Lee's) 1939 classic bearing the same title, has been written by two stratigraphers and a metamorphic geologist to provide an up-to-date survey of the subject. It is based mainly on the immense amounts of both published and unpublished work done since the foundation of the People's Republic.

The book contains a total of 20 chapters, divided into four main parts. Part I ("Background") briefly reviews the development of geology in China and the physical features of the country. Part II ("Stratigraphy") is the backbone of the book, consistent with the dominant interest of the authors. Here, in the first chapter the stratigraphic terminology employed in the book is reviewed and a synopsis of the stratigraphic evolution of China is presented. The next three chapters deal with the Archaean and the Proterozoic eons and the Sinian system. Nine of the remaining ten chapters of Part II treat individual systems from the Cambrian to the Cretaceous, while the last describes, too briefly perhaps, the Cenozoic. In each chapter sedimentary rocks are discussed in terms of stable (platform), mobile (geosynclinal) and transitional sedimentation types — this was an unfortunate choice, which makes understanding of former sedimentary environments in terms of present-day settings difficult. Although boundary and correlation problems are considered for each system, palaeobiogeographic provinces are touched upon only in chapters on the Carboniferous and the Permian systems.

Part III ("Magmatic and Metamorphic Rocks of China") contains two chapters, one each for the two major rock groups. Here the treatment is mainly regional and chronological.

In the last part ("Geotectonic Development of China"), two chapters are devoted to the tectonic framework and geotectonic units, and the geotectonic

development of China respectively. Although much lip service is paid to plate tectonics, and the few palaeotectonic cross-sections are drawn in basic plate-tectonic terms, the underlying framework in both of these chapters is based on an unhappy marriage between a Soviet-style fixist philosophy and plate tectonic mobilism. The descriptions and arguments are made even more difficult for the reader to follow because of the authors peculiar employment of familiar terminology such as aulacogen and continental margin.

A serious limitation of the book is the almost complete lack of reference to foreign or cooperative research on Chinese geology. For example, Molnar and Taponnier's epoch-making studies on the neotectonics of China are not even mentioned. Further, there is no reference to the Franco-Chinese work on Tibet (absence of mention of the geophysical results is especially glaring), nor to the important magnetostratigraphic work by Liu Dongsheng and his co-workers on the loess deposits. Such omissions have in places led to some rather odd conclusions, such as the supposed late Mesozoic origin

and Cenozoic inactivity of the Altyn-Tagh fault.

The paucity of sketch-maps showing particular geological relationships and outcrops adds to the problem of comprehending both local and regional details, so the book is difficult to use to reinterpret the data in terms of models other than the authors'. Despite its deficiencies, however, The Geology of China is a must for those interested in the regional stratigraphy of this country. A subject and a stratigraphic index (both in Pinyin transliteration and in the original Chinese characters) increase the value of the book. as do the 19 black-and-white plates of fossils and photomicrographs of representative lithologies. However, readers would be well-advised to keep at hand either one of the post-1980 comprehensive editions of the Times Atlas or the Zhonghua Renmin Gongheguo Fen Sheng Dituji, for many of the places mentioned in the text are not on any of the maps in the book.

A diverse life

Colin Townsend

Community Ecology. Edited by Jared Diamond and Ted J. Case. Harper & Row: 1986. Pp.665. \$37.50, £16.95.

Suppose, for the sake of argument, that the genetic code, instead of being determined solely by DNA, was co-determined by seven classes of macromolecule. Suppose, too, that in a given species the relative role of the macromolecules varied with age, season, weather conditions and time since the last glaciation, and also tended to differ between large and small species, ectotherms and endotherms, and herbivores and carnivores. If this were true, we would surely not have our present complete understanding of the code. And yet, as the editors of this volume point out, this is exactly the problem that ecologists face in trying to explain how the abundances of interacting species in a community are co-determined by competition. predation, herbivory, disease, parasitism, mutualism and disturbance. Later in the book we are told that studying ecology resembles what it would be like to conduct a chemistry experiment if the chemist were only a few angstroms long and lived for only a few microseconds!

Attempts to solve the daunting problems of variability and scale in community ecology demand a diversity of methodologies to obtain the data and a diversity of models to interpret them. The methods

include laboratory experiments, field observations, experiments in the field, "natural" experiments involving comparative observations at several contrasting outdoor sites, and reconstructions based on historical records in library and museum archives and in fossil assemblages. All figure prominently in this stimulating collection of 33 essays by 35 authors (34 from North America and one from England). The book is written with the professional researcher in mind, but undergraduates will find much of the material accessible.

Each of the five sections of the book opens with a scene-setting chapter. The first, by Jared Diamond, compares the merits of the different experimental approaches and is followed by an account of probably the most ambitious laboratory experiment on community assembly yet attempted — Michael Gilpin and his coworkers describe how the results from 28 species of fruit fly studied singly can be used to predict, with surprising accuracy, the outcome of pair-wise interactions or ten species combinations.

Section 2 is concerned with species introductions and extinctions. Competition between species for food or space is potentially a potent force in the structuring of communities, with species co-existing only if they exhibit some minimal differences in their resource requirements. If this potential is realized (and there is much debate about the point), competition must operate through a process of selective extinction. Michael Moulton and Stuart Pimm have come up with a novel

analysis of historical data to address this question. Records of success or failure of over 100 introductions of exotic bird species to Hawaii during the past 125 years permit calculations of how a species' risk of extinction depends on the number and morphological closeness of other species in the community—a role for competition is indicated in this case.

Section 3 discusses the problem of the appropriate choice of spatial and temporal scale in investigations of community ecology, and Section 4 contrasts equilibrium and non-equilibrium theories of community ecology. A recurring theme in these sections, and elsewhere in the book, is the importance of historical data. Paradoxically, although those who study modern communities regularly debate whether communities are at equilibrium, rarely have they consulted the fossil evidence. Margaret Davis emphasizes that on any time scale from a decade to 100,000 years climate does not fluctuate about a mean value, but exhibits long-term trends. Her data for forest trees, and those of Thomas Van Devender derived from plant and animal fossil remains in packrat middens in the Chihuahuan Desert, emphasize how communities have frequently become dismantled and reshuffled as species shift their geographical location differentially in response to changing climate.

The final sections deal with the variety of forces structuring communities and with the variety of kinds of community that exist. The message is that there is no single model to describe all communities - some are structured mainly by competition, some by predation, some by unpredictable disturbances and so on - but neither is every community unique. Thomas Schoener makes an initial assault on the problem of defining a minimum number of properties of organisms and environments that will enable us to say, for example, that for organisms of Type A, in environments of Type B, the dominant structuring force(s) will be of Type C (D, etc.). But there is still a long way to

Thirty years ago, a book about the multi-species level of ecological organization would probably have dealt almost exclusively with the flux of energy and nutrients between the environment and the community. More popular today is an approach to the understanding of multi-species assemblages based on knowledge of the dynamics of the constituent species populations. Indeed, the old distinction between population ecologist (a student of the abundance and distribution of individual species populations) and community ecologist seems to be fast breaking down.

Colin Townsend is a Lecturer in the School of Biological Sciences, University of East Anglia, Norwich NR47TJ, UK.

Bird cake

John Andrews

The Sparrowhawk. By Ian Newton. Poyser, Town Head House, Calton, Waterhouses, Staffordshire, UK/Buteo, PO Box 481, Vermillion, South Dakota 57069, USA:1986. Pp.396 + plates. £16, \$35.

IN THE battle being fought in many countries to protect rare or declining species. wildlife conservationists are often severely handicapped by lack of knowledge. What are the species' numbers and distribution? What are its requirements, and how can these be accommodated in a changing environment? Often the best we can do is to make an informed guess, always running the risk that error will harm the subject of our concern and weaken our modest influence still further. Against this background, Ian Newton's study of the sparrowhawk (Accipiter nisus) is valuable on two counts. First, it answers many of the questions relevant to the conservation of a bird much affected by human activities. Second, the research methodology and some of the conclusions may, with care, be applied to other accipiters and so advance research on them also.

Sparrowhawks breed in woods and forests across the Palearctic region from Ireland to Japan. In winter most of the boreal birds move south into the Middle East, India and south-east Asia. Close relatives occupy North America, Africa and southern Asia, the whole genus comprising about 50 species worldwide. Few escape the influence of mankind.

In Britain, progressive clearance reduced forest cover to 5 per cent of the land surface by the mid-nineteenth century, and accordingly restricted sparrowhawk distribution: then came the development of game preservation, and an era of intense persecution. Nonetheless, these evasive birds held on in small numbers, thinly but generally present over most of the country until, recently, organochlorine pesticides eliminated them from much of their range. Now, legal protection and, more importantly, changes in pheasant rearing methods have much reduced deliberate killing; afforestation has doubled the potential habitat and controls on organochlorines have permitted a rapid recovery in numbers over most of the country.

Newton, who is a senior ornithologist with the Natural Environmental Research Council, began his study of the species 14 years ago, selecting two areas of Scotland where he sought to trap and ring all individuals present and to find all their nests. From this basis he was able to explore the bird's ecology, making his own practical experiments to test hypotheses as the pro-

ject developed and drawing on other researchers' findings. The work was complicated (but made more rewarding) by the fact that male sparrowhawks are half the weight of the females, so that they differ greatly in habitat usage, range of prey taken and response to factors such as weather and inter-specific competition (not to mention being killed by their own fair sex!).

Many individual birds were studied throughout their lives, enabling Newton to provide here a detailed account of the species' hunting and prev selection, dispersal and migration, breeding mortality and population trends, and of the human impact on their well-being. Much of the material has already appeared in journals, but, like a cake, the book's ingredients gain from being mixed and cooked by a skilful hand. The text is supplemented by crisp monochrome photographs and line drawings, while copious figures present results graphically with the supporting data set out in appendices. There is a good bibliography and an extensive, helpful

Ian Newton has a well-deserved reputation for sound research and for presenting his results in a carefully reasoned and readable manner. *The Sparrowhawk* is well up to expectations; it will be enjoyed by amateur ornithologists and professionals alike.

John Andrews is Head of Conservation Planning at the Royal Society for the Protection of Birds, Sandy, Bedfordshire SG19 2DL, UK.

The sooty owl from Birds of Eucalypt Forests and Woodlands: Ecology, Conservation, Management. Published by Surrey Beatty & Sons Pty, 43-45 Rickard Road, Chipping Norton. The case for life as a cosmic phenomenon

from F. Hoyle and N.C. Wickramasinghe

The arguments in support of life as a cosmic phenomenon are not readily accepted by a culture in which a geocentric theory of biology is seen as the norm.

A LEADING article in a recent issue of Nature explained that we had ourselves to blame for experiencing difficulties of an unusual kind in the publication of referencing of our work1. Our fault was that we had become caught up in the eccentric doctrine of panspermiology, a doctrine for which there was said to be little or no evidence. We have now been invited by the editor of Nature to explain why we differ from his judgement and why in our opinion there is indeed evidence in favour of our position. In our experience, people who become eccentric usually do so through a mental discontinuity, whereas we would claim to have progressed by a series of comparatively small steps over many years, with each step rather cautiously tested by either observation, experiment or calculation using generally accepted methods of deductive science.

Our ideas began in the middle 1950s with qualitative considerations on the nature of interstellar grains and with a straightforward generalization to interplanetary conditions of the well-known Urey-Miller prebiotic experiment². By the early 1960s we had added a refractory carbonaceous component to the ice-grain model of van de Hulst' and had begun to calculate the extinction of starlight to be expected from complex mixtures of ice and carbonaceous particles ". The correspondence between our results and the observed interstellar extinction of visible starlight was tolerable but not really good in view of the many adjustable parameters that were present in the calculations.

Eventually we discovered that appreciably better agreement could be obtained between observation and calculation provided the real part of the refractive index of interstellar grains was low, say 1.15, instead of being 1.3 as for ice or ~2.4 as for carbonaceous particles. A low refractive index turned out to be much better than the many-parameter adjustments we had formerly used. But what material could have a refractive index as low as 1.15? In seeking an answer to this question it was important that the grains be largely made up of cosmically abundant elements, because the amount of the observed extinction is so considerable that only abundant elements will suffice to give the necessary quantity of grains. Of materials based on common elements only solid hydrogen would have the required low refractive index it seemed. So for a while we investigated this possibility and

became enthusiastic about it ⁹. The trouble, however, turned out to be that solid hydrogen was too volatile and would evaporate away¹⁰. So it came about that we were left with an unsolved problem, and we had to put it aside for a decade until quite new ideas suggested themselves.

Organic polymers

From calculations made in 1968 of condensations occurring in large mass flows from astronomical objects we suggested that interstellar grains might contain a magnesium oxide-silicon oxide component and when a so-called silicate emission-band near 10 µm in the infrared was observationally discovered the following year we had a new topic to become en-thusiastic about¹² ¹⁶. Unfortunately as it seemed at the time, our former disappointing experience repeated itself. Following an initial approximate success in matching the laboratory absorption properties of mineral silicate particles to the infrared observations16, the situation did not improve as better laboratory measurements and better observations were made. Discrepancies that were unsatisfactory remained, as they do to this day. It was with mounting frustration that we began to look through mountains of chemical literature, searching for a substance made-up of common atoms with infrared properties similar around 10 µm to the astronomical observations. It was from this intensive literature search that the idea at last dawned on us that organic materials in the form of polymeric structures might make up a major fraction of the interstellar grains', and moreover that similar structures might be present in cometary dust15.

The step from inorganic to organic grains did not seem particularly revolutionary. Organic molecules in the gaseous interstellar medium had been discovered already by radioastronomers, although in nothing like the quantity of the grains, while as long ago as 1956 Platt had suggested the widespread presence of very tiny organic grains19. Still pursuing the infrared problem, we eventually found that among organic materials polysaccharides gave the best correspondence to the astronomical data20,21, and it was at exactly this point in our work that we began to experience hostility from the referees of journals and from the assessors of grant applications at what was then the Science Research Council. We realize now that because polysaccharides on the Earth are a biological product we had unwittingly made a contact that is deeply forbidden in our scientific culture, a contact between biology and astronomy. We did not see that we had sinned mortally and were deeply mystified since at first, we thought of polysaccharides as being produced abiologically. Nor did we realize that the cultural taboo that confronted us had already surfaced in 1870, only one year after the inception of this journal.

Only gradually did we come to understand the difficulties of producing very large quantities of organic material by abiological processes²⁵. The Fischer-Tropsch reaction, for example, which produces hydrocarbons from hydrogen and carbon monoxide depends on the use of carefully controlled catalytic surfaces. which would almost surely be quickly poisoned by corrosive sulphur compounds under cosmic conditions (it may be noted that the Fischer-Tropsch process could not be operated profitably to complete with natural oil at \$30 per barrel, even under the most expertly managed terrestrial conditions).

Biological solution

We are not sure of exactly what it was that caused biology to enter our perceptions. but we think it was noticing a series of drawings of a bacterium from which the internal water was progressively dried out. The cell wall remained in place as cavities developed in the interior, eventually yielding a particle of typically the size of an interstellar grain that was hollow. We realized at once that such a particle would behave with respect to visual light. to a close approximation like a particle of low refractive index, just the situation we had been seeking more than ten years earlier in the 1960s. We obtained an experimentally-defermined size distribution of bacteria from a standard manual and were quickly able to calculate how such a size distribution of hollow particles would behave with respect to the extinction of starlight. The result was a truly excellent fit to the astronomical data, the data we had attempted to fit without real success by our many-parameter models in the

On the strength of this result. Dr Shirwan Al-Mufti began to measure the infrared properties of a number of species of bacteria, finding to his and our surprise a remarkable constancy of absorption for

the wavelength range 3.3 to 3.5 µm, and a general constancy for the whole range from 3 to 4 µm (ref 24). If bacteria made up an appreciable fraction of the interstellar grains, as the observed extinction of visible starlight seemed to suggest, it was necessary therefore that the grains must possess the characteristic absorption pattern which Al-Mufti had measured in the laboratory. It happened not long after these experiments that the average absorption properties of grains along the whole path length from the galactic centre to the Earth was measured to a high degree of accuracy by Allen and D.T. Wickramasinghe³. The results, made at no less than 60 wavelengths between 3 and 4 um, agreed with the bacterial experiments to within an accuracy of typically about one small graticule division on a standard Perkin-Elmer pen chart, an accuracy that we, who had hoped for accuracy, found impressive²⁶.

We are aware that astronomers and chemists can be found who will claim that these results are not impressive, because equally good results could be obtained using plausible non-biological materials. Our answer is that equally good results have not been obtained using plausible non-biological materials. Such claims are advanced and listened to only because they are designed to be culturally acceptable, whereas our results, although based on careful observations, experiments and calculations are not culturally acceptable. In such a situation the critic is permitted to say anything at all without being weighed in the balance and found wanting.

Stellar replication

An attempt is often made to saddle us with the criticism that bacteria could not replicate in interstellar space. We have never said that they did. Our model is a cyclic one, with bacteria replicating as a byproduct of star formation in environments where replication can occur 27 29. Following star formation, a fraction of the bacteria produced are expelled into the interstellar medium. Some die, some survive — quite likely only a minority survive to become incorporated in further star formation processes, and so on around the cycle. Biological replication is an exponential process that can immensely outstrip all abiological processes. Granted sustained conditions for the growth of a bacterial culture, a single viable bacterium could grow to a mass of bacteria equal to the Earth in about nine days, a mass equal to the galaxy in about fifteen days, and a mass equal to the whole visible universe in about twenty days.

It is a necessary corollary that bacteria must be space-hardy, unless after arriving here on Earth mutations have destroyed properties which they possess intially was A viable strain of Streptococcus mitis was recovered after two years of exposure to

conditions on the surface of the Moon³¹. Bacteria can be taken down to near zero pressure and temperature without loss of viability, provided suitable care is exercised in the experimental conditions 12.33 Bacteria can survive after exposure to pressures as high as 10 tonnes cm⁻² (ref. 34) and after flash heating under dry conditions at temperatures up to 1,000 K (ref. 35). Viable bacteria have been recovered from the interior of an operating nuclear reactor. A fraction of bacteria remain viable even after extremely heavy flash doses of high energy radiation, upwards of a megarad, while it seems that bacteria can repair themselves continuously in a maintained environment of high radiation intensity, to the extent of repairing tens of thousands of breaks in their nucleic acid stucture 17.38. These are not properties one would have expected to evolve on the Earth, but they are all properties necessary for survival in space. Damage from ultraviolet light, which is often raised as a problem is actually no problem, because ultraviolet light is easily shielded against^{20,10}

An individual comet has only a small mass, but if one considers all the comets that are believed to exist in the presentday Oort cloud, and to have existed over the whole history of the Solar System, their combined mass could well be comparable to that of the outer planets Uranus and Neptune, about 1029 grams. If the ~10" stars of our Galaxy are typically endowed with similar quantities of cometary material, the total cometary mass for the whole Galaxy would be ~10⁴⁰ grams, very close to the mass of the interstellar grains.

We were led from this consideration to think of a swarm of comet-like bodies, present towards the outer regions of the Solar System in its early history, and being made warm in their interiors by radioactive heat, as the likely sites for early biological replication 42. As we put it on one occasion, such an individual cometary interior would be like a vast laboratory with a floor area of some thousand square kilometres and with a height comparable to that of the Empire State Building. If other dwarf stars are mostly like the Solar System, there could be more than 10²⁰ such laboratories in the Galaxy, which makes it only a matter of commonsense we believe to regard such bodies as a more favourable venue for the development of life than the initially sterile surface of a small planet like the Earth, which even today has a biosphere with a mass of not more than $10^{15} - 10^{19}$ grams.

Holding these views, it was easy for us to predict that an important fraction of the dust expelled from comet Halley would be organic in composition, that bacteria in the dust would become hollow as water within them dried out, thereby yielding particles with an average mass density less than I gm cm ', and that organic material at the surface of comet Hallev would be dark43. We have heard astronomers speaking of the surface material of comet Halley as being dark like tar, perhaps without realizing that tar is itself a biological product

It has often been suggested to us that our views might be tested by a suitable satellite experiment. Such an experiment would be expensive and difficult because of high impact speeds, as we saw in the recent Giotto encounter. Another suggestion often made is to send balloons or rockets into the high atmosphere with the aim of recovering viable bacteria from space. This has actually been done, repeatedly. On every occasion viable bacteria were obtained 44-48, and on every occasion the result was discounted because of the possibility, admittedly serious in some cases, of terrestrial contamination. When a result is culturally unacceptable it will always be discounted on some excuse or other. One cannot win that way.

The Earth is perpetually embedded in a halo of cometary material, of which some 1,000 tonnes enter the terrestrial atmosphere each year. Because of the low density of the upper atmosphere, incident small particles of the sizes of bacteria and viruses could land 'soft' without viability being destroyed by flash heating. After intervals ranging from months to years such particles eventually settle to ground level, where they would be added to the already-existing reservoir of bacteria and viruses. It is to the potential interaction of such incoming particles with plants and animals that one can best look for a direct verification of these ideas. For some years we have been much concerned with this interesting and informative mode of verification22.11. It is our opinion that a large body of facts exists to prove the correctness of the general picture outlined above. The topics themselves being in the medical field of epidemiology, would take us far away from the rest of the present article. Besides which, we are about to run out of the space the Editor has kindly allotted us, and so must refer the reader, if any should be interested, to a recent publication entitled: Viruses from Space . We have found it not a little odd to find our views taken more seriously, or at least received more politely, by the medical profession than they have been by astronomers and chemists, for whom we retain not a few rods in pickle.

Detection of an X-ray-ionized nebula around the black hole candidate binary LMC X-1

M. W. Pakull* & L. P. Angebault[†]

* Institut für Astronomie und Astrophysik, TU Berlin, Sekr, PN 8-1, Hardenbergstrasse 36, D-1000 Berlin 12, West Germany † European Southern Observatory, Karl-Schwarzschild-Strasse 2, D-8046 Garching, West Germany

Optical spectra of the black hole candidate X-ray binary LMC X-1 reveal that the system is surrounded by an extended, highly ionized He III region, N159F, which appears to be the long-sought-for example of an X-ray-photoionized nebula. The spatially resolved temperature and ionization structure allows us to measure the previously unobservable extreme ultraviolet (EUV) luminosity of an accreting compact object.

DESPITE a fairly accurate (±3 arc s) Einstein HRI (high-resolution imager) position for the bright (X-ray luminosity $L_X = 2 \times$ 10³⁸ erg s⁻¹) variable X-ray source LMC (Large Magellanic Cloud) X-1 (ref. 1), neither of the previously suggested optical counterparts²⁻⁴ can be excluded on positional ground alone (Fig. 1). The optical properties of the B5 I star R148 (V =12.2 mag) appear normal for its spectral type, including the slight radial velocity and photometric variations^{5,6} which are observed in most supergiants. More promising for an optical identification is the fainter (V = 14.5) O7 III-type star '32', which reveals the variable He II λ4,686 and λλ4,640-4,650 emission⁴⁻⁶ generally considered to be the hallmark of high-luminosity massive X-ray binary (MXRB) optical counterparts. Hutchings et al.6 have suggested that part of the 4,686-Å emission stems from the surrounding H II region N159F (refs 7, 8; see also Fig. 1); but these authors did not elaborate on this potentially important result.

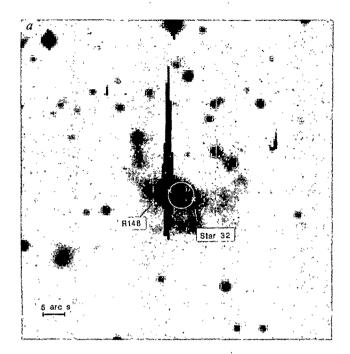

In order to study the reported radial velocity variations⁶ in star 32 which suggest that LMC X-1 might be a black hole (a conjecture which is supported by the interpretation of its extremely soft X-ray spectrum⁹), and to investigate possible X-ray heating effects on the H II region N159F, we have obtained long-slit spectra of this region. Our observations reveal a remarkable ionization structure, suggesting that we have observed the

first example of a spatially resolved X-ray-ionized nebula.

Observations

We carried out two-dimensional charge-coupled device (CCD) spectrophotometry 4 nights in December 1984, using the B&C spectrograph attached to the 3.6-m ESO telescope at La Silla, Chile. Here we are concerned mainly with the results of our observations on 21 December, which were obtained with a reciprocal dispersion of 114 Å mm⁻¹, resulting in a full width at half-maximum (FWHM) resolution of 5 Å in the wavelength range 3,600-5,200 Å. The relatively large width of the slit (2 arcs) made this configuration most suitable for the study of nebular emission from the surrounding H II region N159F. The slit orientations were chosen as shown in Fig. 1b: A, including both candidates R148 and star 32 and B, roughly perpendicular to the former orientation, including star 32. Two longerwavelength CCD spectra which also include the 5,000-6,700 Å region, at a lower resolution of 8 Å, were obtained in May 1985.

The images were flat-field- and extinction-corrected and calibrated in wavelength and flux from the observation of a He-Ar lamp and the spectrophotometric standard stars LLT1020, EG21 and L745-46A, respectively¹⁰, using the image processing facilities IHAP and MIDAS at ESO, Garching.

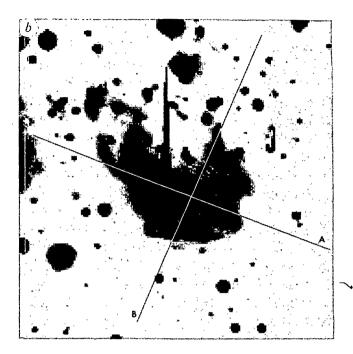

Fig. 1 Direct CCD images of N159F obtained with a Gunn r filter, emphasizing nebular $H\alpha$ emission. The HRI error circle (radius ~3 arc s) of LMC X-1 includes the 12.1-mag B5 I star R148 (strongly overexposed and elongated due to charge transfer effects from the read-out process of the CCD chip) and the presumed O7-III-type optical counterpart (star 32). The image of another fainter star (17 mag) can be seen close to R148. α and α were obtained from the same image with different high and low cuts, in order to emphasize the presence of stars (α) and nebular emission (α). The orientations of the slit in scans A and B are shown in α .

From the reduced images we measured the intensity of several nebular emission lines as a function of position along the slit. As suggested from inspection of Fig. 2, most emission lines are strongly enhanced in the vicinity of LMC X-1. H β , for instance, rises steeply from a background intensity of ~10 to a maximum value of 75 in units of 10^{-16} erg cm⁻² s⁻¹ arc s⁻² (Fig. 3). The extent of ~40 arc s (corresponding to 10 pc at the distance of the LMC) and total flux $F_{\beta} = 10^{-11}$ erg cm⁻² s⁻¹, corrected for interstellar extinction with optical reddening E(B-V) = 0.37

Table 1 De-reddened line strengths relative to H β (=100)							
Emission line	Position 1	Position 2					
[O II] 3,727 Å	285	391					
[Ne III] 3,868	42	8 .					
Ηδ 4,101	. 24	25					
Ηγ 4,340	48	48					
[O III] 4,363	7	1.0					
He I 4,471	2	4					
N 111/C 111 4,640-4,650	<1	<1					
He II 4,686	10	< 0.5					
[Ar IV] 4,711	2	<1 .					
Hβ 4,861	100	100					
[O 111] 4,959	` 171	49					
[O III] 5,007	538	157					
He I 5,876	10	10					
[O I] 6,300	8	4					
[O I] 6,364	. 2	2					
[N II] 6,548	8	10					
Ηα 6,563	. 286	286					
[N II] 6,584	29	34					
[S 11] 6,717*	32	34					
[S II] 6,731*	· 23	24					
$C(H\beta)$	0.582	0.302					

Probable errors in the relative intensity of strong lines $(I_{\lambda}/I_{\beta} \ge 8)$ are dominated by the relative uncertainty in our flux calibration (<10%). The accuracy of weaker intensities is limited by photon noise and reaches $\pm 40\%$ for the faintest detected emission.

(ref. 8), can be accounted for by a Strömgren-sphere model of uniform electron density ($N_{\rm e}=40~{\rm cm}^{-3}$), excited by the ultraviolet flux of an O7 star. Note that the B5 star R148 should not produce a substantial flux of H Lyman-continuum photons.

The [O III] emission is even more enhanced near LMC X-1. The [O III](λ 4,958+5,007)/H β line ratio, which is sensitive to the degree of excitation, peaks at 7.5±0.2, compared with a value of ~2.5 more than 20 arc s away (Fig. 4). The electron temperature derived from the λ 4,363/ λ (4,958+5,007) intensity ratio¹¹ around LMC X-1 is 13,500 K, which is ~5,000 K higher than in the more distant parts of the H II region.

Table 1 lists additional emission line intensities measured close to LMC X-1 and \sim 1.3 arc min away (positions 1 and 2, respectively; see Fig. 3a). Note the increasing ionization towards LMC X-1, as revealed by the [O II] $\lambda\lambda$ 3,726-3,729/H β and [Ne III] λ 3,868/H β line ratios at positions 1 and 2. To produce the high nebular excitation, the effective stellar temperature should exceed \sim 45,000 K (refs 12, 13); however, this is inconsistent with the $T_{\rm eff}$ = 35,000 K determined from the IUE (International Ultraviolet Explorer) study of star 32 (ref. 8).

The most convincing evidence for the presence of a source of high excitation is provided by our detection of extended He II λ 4,686 emission ('He III region', Figs 2, 5) with a diameter of 24 arc s, corresponding to 6 pc in the LMC. The formation by recombination of doubly ionized helium requires a substantial intensity of He⁺ Lyman-continuum photons ($h\nu > 54$ eV), which cannot be provided by even the hottest normal O-stars, as shown by the observation that this transition is never present in the spectra of normal H II regions but can be quite strong in planetary nebula (PN) with central star temperatures of $\sim 10^5$ K.

A PN-type nature of the He III region is, however, ruled out on the basis of the extreme population I environment in N159F and the large extent compared with the diameters of PN in the LMC, which do not exceed 4 arc s (ref. 14). Collisional ionization and excitation in a supernova remnant (SNR) shock can most probably also be excluded, as there is no indication of extended X-ray emission from LMC X-1¹⁵. Furthermore, our red spectra (see Table 1) do not show enhanced forbidden lines

^{*} Values obtained from observations with the 2.2 m telescope.

Table 2 Observed parameters for the X-ray-ionized nebula N159F around LMC X-1

	!
 X-ray spectrum	$L_{1-10 \text{ keV}} = 2 \times 10^{38} \text{ erg s}^{-1};$ thermal bremsstrahlung, $kT = 2 \text{ keV},$ $N_{12} = 9 \times 10^{21} \text{ cm}^{-2}$
Stellar spectrum	O7, $T_{\text{eff}}^1 = 37,000 \text{ K}$, $M_{\text{V}} = -5.0$, E(B-V) = 0.37
Ambient electron density	$N_e = 40 \text{ cm}^{-3}$, probably smaller near LMC X-1
Hβ luminosity	$L_{\rm H\beta} = 3.2 \times 10^{36} \rm erg s^{-1}$
He 11 λ4,686 luminosity	$L_{4,686} = 1.5 \times 10^{35} \text{ erg s}^{-1}$
H II region radius	$r_{\rm H}$ II = 5-6 pc
He III region radius	$r_{\rm He}$ III = 3 pc
O III electron temperature	$T_{\rm e} = 13,500$ K in the He III region
	9,000 K outside

due to low-ionization species such as O I, S II and N II often exhibited by SNRs¹⁶. Also, the λ 4,686 emission has the same (instrumental) width of 170 km s⁻¹ (FWHM) and radial velocity of 261 ± 10 km s⁻¹ (derived from our higher-resolution spectra) as the lower-excitation lines, suggesting that it is not produced in the high-velocity knots observed in many SNR¹⁷. Rejecting a PN or SNR nature, we are left with the hypothesis that LMC X-1 is responsible for the formation of the He-III region in N159F.

He II $\lambda 4,686$ photon counting

Before discussing our findings in the context of increasingly detailed models for X-ray-ionized nebula¹⁸⁻²², we take advantage of the 'photon counting' property of the He II $\lambda 4,686$ line in order to measure the hitherto unobservable EUV flux from LMC X-1.

Although our spectrophotometric mapping of N159F is not complete we can reasonably estimate a total flux $F_{4,686} = 1.2 \times 10^{-13} \,\mathrm{erg} \,\mathrm{cm}^{-2} \,\mathrm{s}^{-1}$ in the $\lambda 4,686$ line, assuming that our scans are representative of the spatial distribution of the emission. Correcting for interstellar absorption towards LMC X-1⁸ and taking 52 kpc for the distance to the LMC, we find (within a factor of 2) an emission-line luminosity $L_{4,686} = 1.5 \times 10^{35} \,\mathrm{erg} \,\mathrm{s}^{-1}$, this being proportional to the absorption rate of He⁺ Lyman-continuum photons, Q_4' , in the nebula:

$$Q_4' = \int_{54 \text{ eV}}^{\infty} L_{\epsilon} / \varepsilon (1 - \exp(-\tau_{\epsilon})) d\varepsilon$$

$$= \frac{L_{4,686}}{h\nu_{4,686}} \frac{\alpha_{\text{B}}(\text{He}^+, T)}{\alpha_{4,686}^{\text{eff}}(T)} = 2 \times 10^{47} \text{ s}^{-1}$$
(1)

where ε is the photon energy, $L_{\rm e}/\varepsilon$ is the photon number spectrum of LMC X-1 (emitted photons s⁻¹ keV⁻¹), $\alpha_{\rm B}$ (He⁺, T) the recombination coefficient summed over all levels above the ground state and $\alpha_{4,686}^{\rm eff}$ (T) the effective recombination coefficient for the emission of He II $\lambda 4,686$ photons (luminosity $L_{4,686}$), carrying an energy $h\nu_{4,686}$. Note that the ratio of these

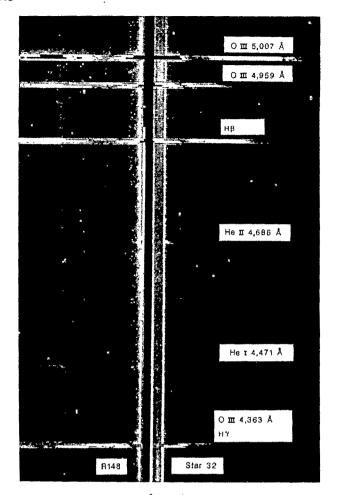

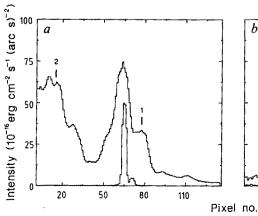

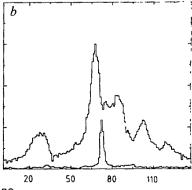

Fig. 2 A section of the 114 Å mm^{-1} two-dimensional spectrum (scan A) with the slit orientated in order to include R148 and star 32. The stellar continua appear as black (R148) and grey (star 32) vertical bands in this representation. The high and low cuts were chosen so as to emphasize faint nebular emission. Note in particular the extended distribution of He II $\lambda 4,686$ emission which peaks at the position of star 32. One pixel corresponds to 1.17 arc s × 2 Å.

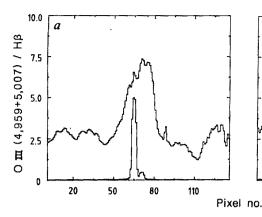

coefficients (\sim 5.2) depends only weakly on the electron temperature.

The optical depth due to He⁺, $\tau_{\varepsilon} = \int_{0}^{\infty} \sigma_{\varepsilon} N_{\text{He}^{+}} ds$ (where s is distance and σ_{ε} is the photoionization cross-section of He⁺, which decreases as ε^{-3} above the threshold of 54 eV) can be estimated by noting that He⁺ is the prevailing ionization stage outside the central parts of the He III region. This is shown by the fact that the (reddening-corrected) He/H recombination line ratio here, $I_{4,471}/I_{\beta} = 0.030 \pm 0.002$, implies a He⁺ abundance of

Fig. 3 Intensity of nebular $H\beta$ emission as a function of position along the slit (a, scan A; b, scan B). The nearby continuum flux has been normalized appropriately and subtracted to correct for the contribution of the stellar emission and H β absorption. The continua due to R148 and the 10 times fainter star 32 (scan A) and star 32 (scan B); which were scaled down by arbitrary factors, are shown in the lower curves to display their position with respect to the nebular emission along the slit. Note the strong enhancement of the emission nearthestars over a background level of 15 × 10⁻¹⁶ erg cm⁻² s⁻¹ (arc s)⁻². Marks 1 and 2 show positions where the nebular spectra summarized in Table 1 were extracted. 1 pixel = 1.17 arc s.

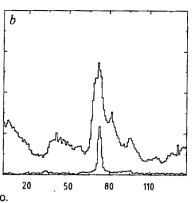

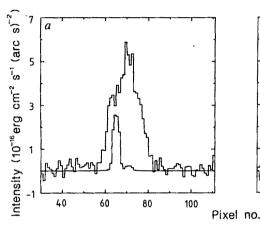

Fig. 4 The [O III] $(\lambda\lambda 4,959+5,007)/H\beta$ line ratio as a function of position along the slit (a, scan A; b, scan B). The lower curves are scans of the stellar and nebular continuum. The maximum value of 7.5 is reached near the position of star 32. 1pixel = 1.17 arc s.

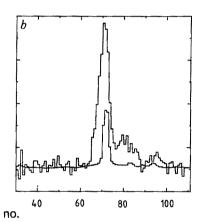

Fig. 5 The He II λ4,686 intensity as a function of position along the slit (a, scan A; b, scan B). Thd lower curves are scans of the stellar and nebular continuum. There is an unresolved component present due to stellar emission from star 32. The extended emission has a diameter of 24 arcs (He III region), corresponding to 6 pc at the distance of the LMC and is centred within 1 arcs on star 32.

 0.070 ± 0.005 , which is in fair agreement with the total average He abundance of 0.085 measured in LMC H II regions²³. A shell with a thickness of 3 pc and a He⁺ density of 3 cm⁻³ has an optical depth of ~40 at 54 eV. The nebula becomes optically thin, however, for He⁺ Lyman-continuum photons above $\varepsilon_u \approx 0.2-0.3$ keV. Accordingly, we can approximate Q_4' by

$$Q_4 = \int_{54 \, \text{eV}}^{\varepsilon_u} L_{\varepsilon} / \varepsilon \, d\varepsilon \tag{2}$$

provided that the intrinsic spectrum does not fall off too rapidly below $\varepsilon_{\rm u}$. At higher photon energies, K-edge photoionization of heavier elements, notably of oxygen at 0.53 keV, is the main opacity source, but these photons are less important for the He ionization balance.

The X-ray spectrum of LMC X-1, which has been observed between 0.6 and 20 keV with the HEAO-1 (High Energy Astrophysical Observatory) A2 MED and HED and Einstein SSS experiments⁹ and, coordinated with our optical investigation, with the Exosat observatory (S. Ilovaisky, personal communication), exhibits relatively strong low-energy absorption with an equivalent column density $N_{\rm H}$ of $(9\pm2)\times10^{21}$ equivalent H atoms cm⁻². Combining the column density with the optical reddening, E(B-V)=0.37 (ref. 8), we obtain the ratio $N_{\rm H}/E(B-V)=(2.4\pm0.6)\times10^{22}$ H atoms cm⁻² mag⁻¹, which is four times higher than the galactic value but agrees well with the LMC gas to dust ratio deduced from interstellar Lyman- α absorption profiles²⁴.

We note that the contribution from the H II Strömgren sphere $(r=5 \text{ pc}, N_e=40 \text{ cm}^{-3}; \text{ see Table 2})$ amounts to only 7% of the total equivalent column density, implying that most of the X-ray and optical absorption is due to an extended neutral envelope, visible in 21-cm surveys, with a total column density of 6×10^{21} H atoms cm⁻² (ref. 25).

Assuming that the kT=2 keV thermal bremsstrahlung model which represents a satisfactory fit to the Exosat ME (0.7-10 keV) observations of LMC X-1 ($L_{\varepsilon}=1.4\times10^{38}$ $g_{\rm ff}(\varepsilon)$ exp $(-\varepsilon/2$ keV) erg s⁻¹ keV⁻¹, where $g_{\rm ff}$ is the Gaunt factor²⁶; S. Ilovaisky, personal communication) can be extrapolated into the EUV,

and anticipating that photoelectric absorption between the X-ray source and the nebula is negligible (see below), we can integrate the differential photon rate L_e/ε to find (from equation (2)): $Q_4=3(4)\times 10^{47}$ photons s⁻¹ for $\varepsilon_{\rm u}=0.2$ (0.3) keV. The close agreement, within a factor of 2, with the value of Q_4 derived from He II $\lambda 4,686$ photon-counting arguments supports the validity of our approach, at least to a first approximation.

Because a power-law model with an energy spectral index $\alpha=1.7\pm0.1$ in the range 0.6-3 keV resulted in a substantially better fit to the Einstein SSS data⁹, we have also investigated how far this model might be valid at lower energies without violating our photon-counting constaint (equation (2)). If the power law extended down to 54 eV, we would expect a $\lambda4,686$ flux 50 times larger than actually observed. In order to produce the observed $\lambda4,686$ luminosity, the intrinsic X-ray spectrum from LMC X-1 should either be cut off below 0.2 keV or substantially flatten (α < 0) between 0.5 and 0.3 keV. The latter alternative qualitatively agrees with the 'cool disk' model²⁷ proposed to explain the spectra of accreting black holes in their high state.

Are the derived He⁺ Lyman-continuum flux from LMC X-1 and the ambient gas density consistent with the observed extent of the He III region? In the optically thin case the radius r_R of this region can be estimated by equating the rate of photoionization and recombination:

$$r_{\rm R} = \left(\frac{L_{\rm X}\gamma}{4\pi N_{\rm e}\alpha_{\rm B}({\rm He}^+, T)}\right)^{1/2} \tag{3}$$

where γ is the photoionization rate coefficient normalized to unit source intensity²¹:

$$\gamma = L_{\rm X}^{-1} \int_{\rm 54\,eV}^{\infty} L(\varepsilon) \sigma(\varepsilon) \frac{{\rm d}\varepsilon}{\varepsilon} \tag{4}$$

In the optically-thick limit, recombination occurs roughly at the Strömgren radius:

$$r_{\rm S} = \left(\frac{3Q_4}{4\pi N_{\rm He}^{++} N_{\rm c} \alpha_{\rm B}({\rm He}^+, T)}\right)^{1/3}$$
 (5)

Inserting the observed parameters from Table 2, we find $r_R \simeq r_S \simeq$ 2-3 pc, in good agreement with the radius of the observed He II $\lambda 4,686$ emission line region.

Here we have assumed that the He III region is observed in a static situation; that is, that the ionization front moving as $r(t) = r_{\rm eq}(1-\exp(-t/\tau_{\rm He II}))^{1/3}$ (where $\tau_{\rm He II} = (N_{\rm e} \alpha_{\rm B}({\rm H_e^+},T))^{-1}$ is the He⁺⁺ recombination timescale) has reached its equilibrium extent, $r_{\rm eq}$. $\tau_{\rm He II}$ (\approx 400 yr for $N_{\rm e}$ = 40 cm⁻³) therefore sets a lower limit to the time LMC X-1 has been X-ray active, and provides the timescale with which the structure of the He III region will react to variations of X-ray input from LMC X-1.

In order to estimate the fraction of doubly ionized He, we use the He II $\lambda 4,686/H\beta$ recombination line ratio, $I_{4,686}/I_{\beta}$, which reaches a maximum value of 0.095 ± 0.010 (corrected for stellar contribution and reddening) around star 32.

Using

$$\frac{\int N_{\text{He}^{++}} N_{\text{e}} \, ds}{\int N_{\text{H}^{+}} N_{\text{e}} \, ds} = \frac{I_{4,686}}{I_{\beta}} \frac{\alpha_{\beta}^{\text{eff}}(T)}{\alpha_{4,686}^{\text{eff}}(T)} \frac{h\nu_{\beta}}{h\nu_{4,686}}$$
(6)

and a He abundance of 0.085 (ref. 23), we find that, averaged over the line of sight towards LMC X-1, the ionization fraction amounts to $\overline{N_{\text{He}}}^{++}/\overline{N_{\text{He}}} = 0.10 \pm 0.01$. Even taking into account that the H II zone around star 32 is 2-3 times larger than the $\lambda 4,686$ emission line region, and allowing for a background contribution from N159F of 30% to the observed H β intensity, we find that He appears not to be fully ionized ($N_{\text{He}}^{++}/N_{\text{He}} \approx 0.4$) in the inner parts of the He III region, unless the density there is lower than in the ambient H II region. A decreasing density and the increase of temperature towards the X-ray source suggests an isobaric, rather than constant-density, cloud (see below).

Keeping in mind the uncertainty involved in the measurement of the de-reddened $\lambda 4,686$ flux, the fact that the extent of the He III zone reflects a time average of the X-ray luminosity, and that we did not take into account the diffuse radiation field from recombinations and transitions of heavy elements, we feel that our modified 'Zanstra temperature' argument provides a first clue to the otherwise unobservable EUV part of the emission from an accreting compact star.

So far we have not fully exploited the information provided by our spatially resolved spectroscopy concerning the ionization and temperature structure of the nebular region around LMC X-1. First, we note that the centre of gravity of the He II λ4,686 intensity profile in scan A (Fig. 5) coincides within 0.6 arc s with star 32. Here we have discarded the unresolved stellar component, which contributes ~10% to the observed flux. Scan B exhibits a more strongly peaked λ4,686 profile near star 32, with lower-intensity emission ~10 arc s to the north. Again, the centre of gravity of the extended emission deviates by <1 arc s from the star. We take this as convincing evidence that star 32 is the optical counterpart of LMC X-1.

A second point concerns the presence of a relatively strong nebular continuum in N159F. Here we find that the intensity in the continuum, I_{ν} (measured near $H\beta$), closely follows the variation of I_{β} along the slit (see Fig. 3), and has an I_{ν}/I_{β} ratio of $(5.0\pm0.6)\times10^{-14}\,\mathrm{Hz^{-1}}$, which is ~8 times higher than the value calculated from atomic processes (free-free, bound-free and two-photon emission²⁸) alone. This result implies an intimate mixture of gas and dust in N159F, which scatters stellar radiation from star 32 (and possibly R148) into our line of sight and also explains the extended ultraviolet continuum emission observed with the IUE around LMC X-1 (ref. 8).

Comparison with models

Drawing on early studies of the physical conditions prevailing in a gas cloud around a strong X-ray source^{18,19}, several investigators have extended the calculations by including important effects such as Auger emission, Compton heating and charge-transfer reactions. The most extensive calculations were per-

formed by Kallman and McCray²¹ and Kallman²², who explored the nebular response to several X-ray input spectra, assuming constant gas density and constant pressure clouds.

For a given X-ray spectrum the ionization and temperature structure depend only on the ratio of X-ray photon flux to particle density, $\zeta = L_{\rm X}/nR^2$ (ref. 18), where n is the particle density at a distance R from the source, provided that the cloud is optically thin. Radiative transfer effects become important for larger values of the column density scaling parameter $(L_{\rm X}n)^{1/2}$ (ref. 21), starting at low photon energies where the opacity is greatest. As shown above, N159F has an optical depth of 40 at the He⁺ ionization threshold, which then quickly drops to values $\ll 1$ for photons with $\varepsilon > 0.2-0.3$ keV.

Model 2 of ref. 21, which assumes a thermal-bremsstrahlungtype spectrum with kT = 10 keV, a luminosity $L_X = 10^3$ erg s⁻¹ and a constant ambient density of 10^3 cm^{-3} , has about the right column density scaling parameter to be compared with the observed X-ray heating and ionization effects around LMC X-1.

Helium is expected to be doubly ionized ($\mathrm{He^{2+}/He} > 0.9$) for $\zeta > 5$ (in cgs units). For increasing distance from the source, different ionization stages coexist, decreasing the relative abundance of $\mathrm{He^{++}}$ to <10% for $\zeta < 0.4$. The low efficiency of highenergy photons for the complete ionization of helium is clearly demonstrated by the model calculations of ref. 20 which assume input spectra with a low-energy cut-off at 1 keV. Here, $\mathrm{He^{++}}/\mathrm{He}$ drops below 0.1 for $\zeta < 100$, implying a He III region which is 16 times smaller than in model 2 of ref. 21. At the same total luminosity the soft ($kT = 2 \,\mathrm{keV}$) spectrum of LMC X-1 provides ~ 5 times more flux below 1 keV than the $kT = 10 \,\mathrm{keV}$ model; therefore, we consider an equivalent spectrum for LMC X-1, with $L_{\rm X} = 10^{39} \,\mathrm{erg \, s^{-1}}$ and $kT = 10 \,\mathrm{keV}$.

At an ambient density $N_{\rm e}=40~{\rm cm}^{-3}$ (Table 2), ionization parameters of 0.4 and 5 translate into distance of 2.6 and 0.7 pc from the X-ray source. The former radius closely agrees with the observed extent of the He II $\lambda 4,686$ emission and with the result of the previous estimate on the basis of simple recombination and Strömgren-sphere arguments.

Moving inward from $\zeta = 0.4$ to 5, the temperature increases from 1×10^4 to 1.8×10^4 K. Our O III observations qualitatively support this type of temperature structure, with T_e increasing by $\sim 5,000$ K from the outer to the inner parts of N159F (Table 2)

For a more quantitative comparison, one must take into account the distribution of O²⁺ ions within the nebula, which strongly deviates from that in model 2 due to the presence of the stellar ultraviolet continuum from star 32. Here the stellar radiation field keeps oxygen doubly ionized throughout the H II region (see Fig. 4), and therefore strongly weighs the observed [O III] line ratio towards lower temperatures.

The presence of the ultraviolet continuum from star 32 has another important effect on the ionization structure of N159F: it removes the H I and He I atoms, thus suppressing charge-transfer reactions. It has been argued²⁹ that this effect increases the column densities N_i^j of several multiply ionized trace elements by factors of 3 to 25, and moves the location of the shell in which a given ion is found outward by a factor of 1.4-6 in radius.

Using the scaling laws $N_i^{\rm i} \propto (L_{\rm X} n)^{1/2}$ (ref. 21) and taking into account the observed abundance in LMC H II regions²³, we can predict interstellar column densities of 5×10^{15} , 5×10^{14} and 8×10^{15} cm⁻² for the ions C IV, N V and O VI, respectively, which have resonance lines in the observable ultraviolet. These values are 1-2 orders of magnitude larger than those in the line of sight towards the galactic massive X-ray binaries HD153919 (ref. 30) and HD77581 (ref. 31) and should therefore be easily detectable in future high-resolution ultraviolet spectroscopy of LMC X-1.

As there is observational evidence for increasing temperature and decreasing density towards LMC X-1, isobaric X-ray nebular models might be more applicable for the situation prevailing in N159F. Here we note only that, according to ref. 22,

the assumption of constant pressure enhances the tendency to thermal instability in the cloud and increases the temperature and ionization gradients. The model spectra predict enhanced forbidden and semi-forbidden line intensities and relative suppression of optically allowed emission lines of highly charged ions, compared with the results obtained under the assumption of constant density.

Discussion

X-ray and ultraviolet studies of several massive X-ray binaries have revealed that these systems are imbedded in strong stellar winds (with typical mass loss rates of 10^{-7} - $10^{-6}~M_{\odot}~yr^{-1}$, where M_{\odot} is the mass of the Sun) emerging from the OB-type companions, which in turn will absorb most of the soft X-ray flux and cause variable P Cyg profiles of ultraviolet resonance lines formed in the wind^{32,33}. However, when the X-ray luminosity exceeds a critical value, the low-Z (atomic number) atoms which dominate the opacity of the wind will be nearly completely ionized. This situation probably prevails in the super-Eddington pulsar SMC X-1, where no indication for wind absorption has been found down to at least 0.5 keV (ref. 34). Following ref. 32 and assuming for simplicity a constant-velocity stellar wind, we find that the ionization parameter in the wind can be expressed

$$\zeta = 1.1 \times 10^{5} \left(\frac{L_{\rm X}}{2 \times 10^{38} \,\mathrm{erg \, s^{-1}}} \right) \left(\frac{a}{2 \times 10^{12} \,\mathrm{cm}} \right)^{-2} \times \left(\frac{v_{\rm w}}{1,500 \,\mathrm{km \, s^{-1}}} \right) \left(\frac{\dot{M}}{10^{-7} \,M_{\odot} \,\mathrm{yr^{-1}}} \right)^{-1} \left(\frac{r_{*}}{r_{\rm X}} \right)^{2}$$
(7)

where r_* and r_X are the distances from the O star and X-ray component, respectively, and \dot{M} denotes the mass loss rate. The units of L_X (2×10³⁸ erg s⁻¹; see Table 1), binary separation a (2×10¹² cm (ref. 6)) and stellar wind velocity v_w (1,500 km s⁻¹ (ref. 8)) have been chosen to match the observed parameters of LMC X-1. Using various mass-loss indices based on the profile of the C IV 1,548-1,550-Å ultraviolet resonance doublet³⁵, which has an absorption equivalent width of 2-4 Å (ref. 8), $10^{-7} M_{\odot}$ yr⁻¹ can probably be considered as an upper limit to the mass loss rate from star 32.

Such high ξ values are more than sufficient to completely ionize H and He (log $\xi > 1.4$), oxygen (log $\xi > 2$) and other low-Z atoms²¹ throughout the wind zone, with the possible exception of the X-ray shadow cast by the O star. Thus, the stellar wind in the LMC X-1 system is largely transparent to soft-X-ray and EUV photons, consistent with our observation that N159F is exposed to most of the EUV photons from an unabsorbed thermal bremsstrahlung or 'cool disk' spectrum.

We have shown that LMC X-1 is not just projected onto N159F but that the source is located within, and interacting with, the extreme population I environment. This has the important consequence that the interstellar medium around the X-ray binary is dense enough ($N_e = 40 \, \mathrm{cm}^{-3}$, Table 2) to reveal observable high excitation features. Keeping in mind that the extent and luminosity of the λ^4 ,686 emission scale with $(L_{\rm X}/n)^{1/2}$ and $L_{\rm X}$, respectively, we find that the surface brightness (intensity), $I_{4,686}$, in this approximation is directly proportional to the gas density; that is, $I_{4,686} \subset N_e$, independent of $L_{\rm X}$. Let us imagine an LMC-X-1-type source in a low-density environment, with $N=0.1 \, \mathrm{cm}^{-3}$ being typical for the general interstellar medium. The He III zone would then be 20 times more extended, emitting a $\lambda 4$,686 intensity of $4 \times 10^{-18} \, \mathrm{erg \, s^{-1} \, cm^{-2}}$ (arc s)⁻² (assuming negligible reddening), which comes close to the limit of detectability for today's instrumentation.

How can we explain the fact that, with the notable exception of LMC X-1, massive X-ray binaries are generally found far away from their birthplaces? According to evolutionary scenarios for MXRB (ref. 36, and references quoted therein)

the supernova explosion creating the compact component introduces an appreciable orbital eccentricity and systemic run-away velocity, $v^{\rm ra}$. When the OB star is sufficiently evolved (evolutionary timescale $\tau^{\rm eV}$) either to emit a strong stellar wind or fill its critical lobe, the system will enter the relatively short ($<10^5$ yr) X-ray phase.

For system parameters representing typical MXRB, $v^{\rm ra} = 40-100~{\rm km~s^{-1}}$ and $\tau^{\rm ev} = 3\times 10^6~{\rm yr}$, runaway distances of $d_{\rm ra} = 200~v_{70}^{\rm ra}~\tau_{6.5}^{\rm ev}$ pc (where $v_{70}^{\rm ra} = v'^a/70~{\rm km~s^{-1}}$ and $\tau_{6.5}^{\rm ev} = \tau^{\rm ev}/10^{6.5}~{\rm yr}$) from the site of formation are envisaged, displacing the X-ray binary far outside the average parent OB association and, thus far from the region of high interstellar density.

The fact that LMC X-1 is located within N159 (diameter 50 pc) argues for an exceedingly small $v^{\rm ra} (\le 20 \, {\rm km \ s^{-1}})$, which is consistent with the upper limit of $40 \, {\rm km \ s^{-1}}$ (ref. 6) to the systemic relative radial velocity with respect to the nebular emission. We cannot exclude with certainty, however, that LMC X-1 was born in one of the nearby OB associations (LH103, LH108) and is by chance now crossing N159F.

We note that the BH candidate system LMC X-3 should have had a different evolutionary history. In the framework of a recently proposed evolutionary scenario for the source³⁷, we find a runaway distance $d_{\rm ra} = 1.8 \, {\rm kpc} \, (v_{70}^{\rm ra} = 2, \, \tau_{6.5}^{\rm ev} = 3.8)$, which explains its location in the outskirts of the LMC more then 2° (corresponding to 2 kpc) away from the nearest region of recent star formation.

A possibily related high-excitation region has recently been discovered around the SNR 1E0102.2-7219 in the Small Magellanic Cloud, where a He II $\lambda 4,686$ -emitting halo surrounds the X-ray and optical remnant³⁸. The X-ray emission and its extrapolation towards lower energies, however, seems to be too weak to account for the ionization. Instead, a fossil H II region created by an ultraviolet flash during the supernova explosion or ultraviolet radiation from the SNR itself were proposed to be responsible for the excitation of the observed He III region.

Yet another candidate X-ray ionized nebula in the Magellanic Clouds was identified in the course of the present study, in the form of a shell-like structure in the light of [O III] centred on the ultra-soft LMC X-ray binary LHG83 (ref. 39). The question of whether the environment of the Magellanic Clouds is particularly favourable for the formation of observable X-ray-ionized nebulae (as seems to be the case for the formation of black holes⁴⁰), or whether some selection effect operates against their detection in the Galaxy, remains to be investigated. Further studies of galactic X-ray binaries at a sensitivity equal to or exceeding that of our observations will be necessary to search for galactic counterparts to N159F.

Conclusions

Our spectroscopic observations of LMC X-1 reveal that the black-hole-candidate binary is surrounded by a spatially resolved He III region, N159F, of ~6 pc in diameter. Within N159F the degree of ionization and the temperature strongly increase towards the X-ray source. We suggest that we are seeing the first example of an X-ray-ionized nebula, which is furthermore embedded in a more conventional H II region excited by the O7 star optical counterpart of LMC X-1 (star 32). Using simple photon-counting computations we have determined the previously unobservable EUV/soft-X-ray spectrum of an accreting compact object from the flux in the nebular He II $\lambda 4,686$ recombination line. Our results suggest that N159F is subjected to an essentially unabsorbed thermal bremsstrahlung (or related) X-ray spectrum, extending towards low energies to at least 0.054 keV. We show that, in contrast to the situation encountered in most galactic massive X-ray binaries, the X-ray luminosity of LMC X-1 is sufficiently high to nearly completely ionize the stellar wind from the early-type companion, which in turn becomes essentially transparent to EUV/soft X-ray photons. Evolutionary models have been shown to explain why strong X-ray binaries are generally located outside regions of enhanced interstellar gas density, implying that observable N159F-type X-ray-ionized nebula are quite rare phenomena.

X-ray photoionization is also thought to play a major role in the formation of emission lines in active galactic nuclei (see refs 41, 42 and referenced therein), and several models of X-rayionized nebulae have been tailored to account for the observed continua and emission lines in these objects. In this context the highly ionized nebula around LMC X-1 might be considered to be a scaled-down version of the narrow-emission-line region in Seyfert-2- and 1.5-type galaxies. Most importantly, the combination of high X-ray luminosity and moderately low ambient gas density realized for LMC X-1 allows a spatially resolved study

2.5-Myr Australopithecus boisei from west of Lake Turkana, Kenya

A. Walker*, R. E. Leakey†, J. M. Harris‡ & F. H. Brown§

* Department of Cell Biology and Anatomy, Johns Hopkins University School of Medicine, 725 North Wolfe Street, Baltimore, Maryland 21205, USA

† National Museums of Kenya, PO Box 40658, Nairobi, Kenya ‡ Los Angeles County Museum of Natural History, 900 Exposition Boulevard, Los Angeles, California 90007, USA § Department of Geology and Geophysics, University of Utah, Salt Lake City, Utah 84112, USA

Specimens of Australopithecus boisei have been found in 2.5-Myr-old sediments west of Lake Turkana, Kenya. The primitive morphology of these early A. boisei suggests that robust and hyper-robust Australopithecus developed many of their common features in parallel and further that A. africanus is unlikely to have been ancestral to A. boisei.

THE 'hyper-robust' hominid Australopithecus boisei is wellknown from several East African Plio-Pleistocene deposits dated between 2.2 and 1.2 Myr (refs 1, 2). It has been thought of variously, as: the northern vicar of the equally well-known A. robustus3; the extremely specialized end-member of the robust clade4; an already developed species which immigrated from another, unknown area⁵; and as representing individuals at the large end of a single Australopithecus species that also encompasses A. robustus and A. africanus⁶.

There is a growing consensus that the east and south African samples are different enough to allow them to be placed in separate species¹⁻⁴. The type specimen of A. boisei is Olduval Hominid $5^{7.8}$.

These two robust species are placed in the genus Paranthropus by some authors9. Although recognizing that the two known samples overlap in time, some have advocated an ancestordescendant relationship with A. robustus giving rise to A. boisei. Perhaps the most compelling recent evidence for this last view

is Rak's exemplary study of the structure and function of the australopithecine face4. He has followed an evolutionary scheme in which the origins of the robust clade are in A. africanus, which is thereby removed from consideration as a human ancestor¹⁰. This scheme has not found universal acceptance^{11,12}.

Localities

Prospecting was carried out in 1985 in Pliocene sediments to the west of Lake Turkana, Kenya. It led to the recovery of two A. boisei specimens. A cranium and a partial mandible were discovered at two separate localities: sediments in the Lomekwi and Kangatukuseo drainages (see Fig. 1) at approximately 3°45′ N, 35°45′ E.

The general dip of strata is to the east in the Lomekwi drainage, but the strata at Lomekwi I from which the cranium was derived are deformed into a syncline by drag along a fault that truncates the section about 50 m east of the site. Several small faults cut the section west of the site, but it has been possible to link the

short sections together by analysis of volcanic ash layers in the sequence. The total thickness of section immediately surrounding the site is less than 15 m, and the volcanic ash layer which caps the section is compositionally indistinguishable from Tuff D of the Shungura Formation. Earlier¹³, this tuff was referred to the informally designated Upper Burgi Tuff of the Koobi Fora Formation. With more numerous analyses it is now clear that the Upper Burgi Tuff also correlates with Tuff D, and an additional correlation datum is provided between the Shungura Formation and the Koobi Fora Formation. Tuff D has been

dated at 2.52 ± 0.05 Myr¹⁴. This age is an average computed from samples from the Shungura Formation in Ethiopia, and from the correlative unit at Kangatukuseo. The cranium derives from a level 3.8 m below Tuff D. Around 10 m below Tuff D there is a second ash layer. In the Lokalalei drainage, about 4 km northwest of the site, there are three ash layers exposed in sequence. The lowest correlates with a tuff in submember C9 of the Shungura Formation, and the upper two correlate with the two ash layers exposed at the site of the cranium. On this basis, the cranium is shown to lie within strata correlative with submember C9 of the Shungura Formation. Based on the K/Ar chronology of the Shungura Formation and scaling on the basis of constant sedimentation rates there, the cranium is estimated to be 2.55 Myr old. Using palaeomagnetic polarity boundaries as the basis of chronological placement, the age of the cranium would be ~2.45 Myr, as there is a slight discordance between the two chronologies¹⁵. Therefore, we believe that the age of the cranium can be confidently stated as 2.50 ± 0.07 Myr, including all errors. The sediments from which the cranium derives are overbank deposits of a large perennial river, probably the ancestral Omo.

The mandible from Kangatukuseo III derives from a level about 19 m above Tuff D. Tuff E is not exposed in Kangatukuseo, but it is exposed in the northern part of the Lomekwi drainage, and in the southern Lokalalei drainage. There, sediments correlative with Member D of the Shungura Formation are at least 26 m thick. On this basis, the mandible is assigned to the central part of Member D of the Shungura Formation, the best age estimate for which is 2.45 ± 0.05 Myr. The section is faulted east of the mandible site, and older sediments are exposed along the drainage east of that point. In fact, the entire section exposed in Kangatukuseo lies within an interval from ~25 m above Tuff D to 5 m below that tuff. The mandible was collected from a sandstone layer \sim 6 m thick, deposited by a large river system. Thin basalt pebble conglomerates intercalated in this part of the section show that the site lay near the boundary between sediments deposited by this large river, and alluvial fan deposits derived from the west.

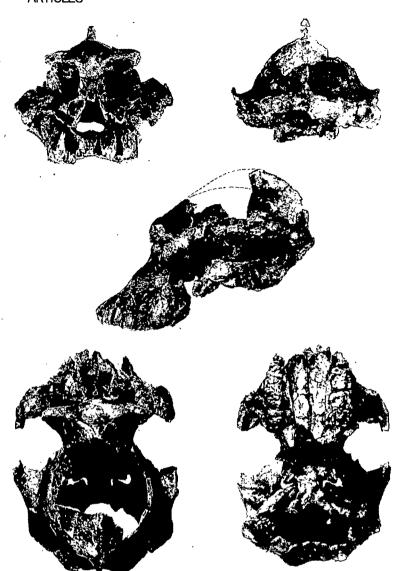

Fig. 2 Anterior, posterior, left lateral, superior and inferior views of cranium KNM-WT 17000.

Scale in cm.

The interval of section from which the australopithecine specimens were collected has also yielded over 200 fossils representing more than 40 other mammalian species (Table 1), including the skeleton of a ground-dwelling colobine and a relatively complete camel mandible. Bovids are the most common elements of the fauna at this level and most represent species that are otherwise known from the lower portion of the Omo Shungura succession. But whereas alcelaphines and impalas predominate at lower horizons west of Lake Turkana, reduncine bovids are the commonest fossils at the australopithecine sites reported here and are taxonomically different from those recovered slightly higher in the sequence. Elephas recki shungurensis is the common elephant at the localities considered here while Notochoerus scotti and Kolpochoerus limnetes are the common suids. Although all three taxa have lengthy Pliocene distributions, the West Turkana specimens closely match samples of these species from Omo Shungura Members C and D-thus supporting the estimate of age derived from the tuff analyses. The age estimate is corroborated by the apparent absence of the elephantids Loxodonta adaurora, Loxodonta exoptata and Elephas recki brumpti, and of the suids Nyanzachoerus kanamensis, Notochoerus euilus, Kolpochoerus afarensis and Potamochoerus sp., all of which occur in older horizons in the upper reaches of the Laga Lomekwi. Also missing from the australopithecine-bearing assemblage are the reduncine bovid

Menelikia lyrocera and equids of the genus Equus, both of which occur higher in the sequence.

Specimens

KNM-WT 17000 is an adult cranium with the following parts missing: all of the tooth crowns except a half molar and the right P³; some facial bone fragments which have spalled off the infilled maxillary sinus; most of the frontal processes and temporal plates of the zygomatics; the zygomatic arches themselves; a large part of the frontal and parietals superiorly (but a piece of the sagittal crest on the anterior part of the parietal is preserved); parts of both pterygoid regions inferiorly and the posterior part of the maxilla and palate on the right side; and the inferior part of the nuchal region of the occipital. There is no bilateral asymmetry and all bony contacts are sharp. There is no evidence of any plastic deformation and the brain case has retained its spheroidal shape (Fig. 2).

It is a massively-built cranium with a very large facial skeleton, palate and large cranial base, but with a small brain case. The palate and cranial base are roughly the same size as in Olduvai Hominid (O.H.) 5. The cranial base is about the same size as, but the palate is slightly larger than in, KNM-ER 406 (ref. 16). The cranial capacity is 410 ml (mean of five determinations by water displacement with a standard error of 4.32). This measurement is probably accurate since the orbital plates of the frontals,

the cribiform plate region of the ethmoid, one anterior clinoid and both posterior clinoid processes are preserved together with the rest of the cranial base. The missing cranial vault fragments can be reconstructed with fair certainty by following the internal contours all around them. This is the smallest published cranial capacity for any adult fossil hominid, although A.L. 162-28 from Hadar¹⁷ must have been smaller. Given the massive face and palate combined with a small brain case, it is not surprising that the sagittal crest is the largest ever in a hominid. Further, the sagittal crest joins completely to compound temporal-nuchal crests with no intervening bare area¹⁸. The foramen magnum position is far forward as in other robust Australopithecus specimens¹⁹.

The one complete tooth crown, right P³, is 11.5 mesiodistally by 16.2 buccolingually. This is bigger mesiodistally (md) than O.H. 5 (10.9) and smaller buccolingually (bl) (17.0)^{7,8}. These dimensions are completely outside the recorded range for A. robustus (9.2-10.7 md, 11.6-15.2 bl) and at the high end of the range for A. boisei (9.5-11.8 md, 13.8-17.0 bl)²⁰. Only the largest A. boisei mandibles found so far (for example, KNM-ER 729

and 3230²¹) would fit this cranium. It is unfortunate that the region of the occipital which would show the grooves for the occipital and marginal sinuses is missing, but the small sigmoid sinuses appear to have no contribution from transverse ones. Thus we feel that enlarged occipital and a marginal sinuses may have been present.

Most of the previously recorded differences between A. boisei and A. robustus have involved greater robustness in the former. In fact for those parts preserved in KNM-WT 17000, the definitions originally given by Tobias⁸ include only two characters that cannot be simply attributed to this robustness. One is that the supraorbital torus is 'twisted' along its length. Subsequent discoveries of A. boisei specimens show that O.H. 5 is extreme in its supraorbital torus development and that others are not so 'twisted'. The other character is that A. boisei palates are deeper anteriorly than those of A. robustus, in which they tend to be shallow all along the length. Recently, Rak⁴ has undertaken a study of the australopithecine face and has documented structural differences between the faces of all four species. Skelton et al.²² have just made a cladistic analysis of

Fig. 3 Occlusal view of mandible KNM-WT 16005. Scale in cm.

early hominids; Table 2 lists some of the characteristics given as typical of Australopithecus species by these authors (see ref. 22 and refs therein) as well as the condition found in KNM-WT 17000. For most features the new specimen resembles A. boisei.

There are some features of KNM-WT 17000 that differ from all other 'hyper-robust' specimens as well as from robust ones. The most obvious and important is the prognathic mid- and lower facial region. In superior view all other robust crania are so orthognathic that only a small part of the incisor region projects past the supraorbital tori. In KNM-WT 17000 the mid-face projects strongly past the tori and the anterior maxilla projects well forwards as a square muzzle. In summary, we regard this specimen as part of the A. boisei clade and view its differences from the younger sample as being either primitive, or part of normal intraspecific variation that has not been documented before, or both.

Mandible KNM-WT 16005 has the body preserved to the M₃ alveoli on the left and the M₂ alveoli on the right. The base is missing. The incisors and canines are, as judged from their roots, relatively very small and the post-canine teeth relatively very large. In its size, shape and proportions, KNM-WT 16005 is very similar to the Peninj mandible²³, except that the P₄ and M₁ of the latter are a little larger and the M₂ a little smaller than this specimen. KNM-WT 16005 is smaller than the mandible which KNM-WT 17000 possessed. Tooth measurements are given in Table 3, and the specimen is shown in Fig. 3.

Although future finds may show that KNM-WT 17000 is well within the range of variation of A. boisei, it is also possible that the differences will prove sufficient to warrant specific distinction. If the latter proves to be the case we suggest that some specimens from the same time period and from the same sedimentary basin (for example, Omo 1967-18 from the Shungura Formation) will be included in the same species. Omo 1967-18 is the type specimen of Paraustralopithecus aethiopicus Arambourg and Coppens²⁴. In our view, the appropriate name then would be Australopithecus aethiopicus.

Conclusions

The new specimens show that the A. boisei lineage was established at least 2.5 Myr ago and further that, in robustness and tooth size, at least some members of the early population were as large as any later ones. Although one authority suggested

that the robust australopithecines became smaller in skull and tooth size with time²⁵, most have pointed out that the available sample showed the opposite, that within A. boisei there has been an increase in size and robustness of the skull and jaws. This was apparently an artefact of sampling and is no longer correct.

Although recognizing that at least some populations of A. robustus and A. boisei overlapped in their time ranges, Rak⁴ hypothesized that the former was ancestral to A. boisei. This is no longer tenable. A. robustus shares with younger examples of A. boisei several features which are clearly derived from the condition seen in KNM-WT 17000. These include the cresting pattern—with the emphasis on the anterior and middle parts of the temporalis muscle—the orthognathism and the deep temporomandibular joint with strong eminence. At the same time KNM-WT 17000 is clearly a member of the A. boisei lineage, as demonstrated by the massive size, extremely large palate and teeth, the build of the infraorbital and nasal areas and the anterior position and low take-off of the zygomatic root.

Therefore, this new specimen shows that A. robustus is a related, smaller species that was either derived from ancestral forms earlier than 2.5 Myr and/or has evolved independently in southern Africa, perhaps from A. africanus. It has been suggested before that A. robustus was derived from A. africanus⁴, but by those who believed A. robustus then gave rise to A. boisei—an interpretation that is now unlikely.

The idea that A. africanus was the earliest species of a lineage in which A. robustus led to A. boisei is challenged by the new evidence. KNM-WT 17000 shows that all known A. africanus share features which are derived relative to it. Many of these same features were cited by White et al.²⁰ in arguing that A. afarensis is more primitive than A. africanus. Features showing KNM-WT 17000 to be more primitive than A. africanus that were also used to distinguish the primitiveness of A. afarensis

Table 3 Tooth measurements of KNM-WT 16005 (mm)

	Mesiodistal	Buccolingual
Left P ₃	10.7	13.8
P ₄	(12.0)	(15.0)
M ₁	15.7	14.3
M ₂	(17.0)	16.7

are: a very flat, shallow palate; pronounced subnasal prognathism; compound temporal/nuchal crests; sagittal crest with emphasis on posterior fibres of the temporalis muscle; an extensively pneumatized squamous temporal, which in KNM-WT 17000 is 11.5 thick just above the supraglenoid gutter; small occipital relative to nuchal plane; pneumatization of lateral cranial base to produce strongly flared parietal mastoid angles; shallow and mediolaterally broad mandibular fossae; tympanics completely posterior to the postglenoid process. In KNM-WT 17000, the asterionic region is poorly preserved, but an asterionic notch was probably present, which is an additional feature also cited to demonstrate the primitiveness of A. afarensis.

Other primitive features found in KNM-WT 17000, but not known or much discussed for A. afarensis, are: very small cranial capacity; low posterior profile of the calvaria; nasals extended far above the frontomaxillary suture and well onto an uninflated glabella; low calvaria with receding frontal squama; and extremely convex inferolateral margins of the orbits such as found in some gorillas. Thus there are many features in which KNM-WT 17000 is more primitive than A. africanus and similar to A. afarensis yet KNM-WT 17000 is clearly a member of the A. boisei clade. Further, although the dating of the South African sites is admittedly still imprecise and populations of ancestral species may survive a speciation event, the time sequence of the fossils is becoming increasingly less supportive of the idea of an africanus-robustus-boisei lineage.

Finally, it is striking that many of the features of this cranium shared by A. afarensis are primitive and not found in A. robustus or later specimens of A. boisei. These primitive featuresshared by KNM-WT 17000 and A. afarensis are almost exclusively confined to the calvaria, despite the largely complete face of KNM-WT 17000 and the existence of several partial facial specimens at Hadar. However, not one individual adult specimen of A. afarensis preserves a facial skeleton attached to a calvaria. This observation raises two alternatives: first, that these features are primitive to the Hominidae and therefore not of great taxonomic value in determining relationships among hominids; second, that, Olson²⁶ has suggested, the specimens identified as

Steep-spectrum radio lobes near the galactic centre

N. E. Kassim, T. N. LaRosa & W. C. Erickson

Astronomy Program, University of Maryland, College Park, Maryland 20742, USA

In a previous paper1 we reported the discovery of an extended steep-spectrum radio lobe located ~34 arc min north-east of the galactic centre (the northern galactic centre lobe). Based on the similarity of the observed properties of this object to the radio lobes observed in the nuclei of Seyfert galaxies2, we suggested that this source may be a manifestation of nuclear activity associated with the compact non-thermal source³ located at the galactic centre. However, no clear evidence for a second opposing lobe was evident from the 80-MHz observations. Here we report observations at 110.6 and 123.0 MHz which confirm the existence of a second steep-spectrum feature, first discovered by Yusef-Zadeh et al.4 at 160 MHz, which extends ~10 arc min to the south-east of the radio source Sagittarius-A. These new observations are in the only frequency range in which it is possible to view both of these features simultaneously and to display their morphology as a function of frequency. At lower frequencies the features are obscured by thermal absorption; at higher frequencies they blend into the background emission. Based on this unique perspective, we propose that these radio sources are related, and associated with activity at the galactic nucleus.

Our observations were made in April-May 1985 with the TPT telescope of the Clark Lake Radio Observatory⁵. This instrument is a T-shaped array of 720 conical-spiral antennas, measuring 3.0×1.8 km, operating in the range 15-125 MHz. The beamwidth in the direction of the galactic centre is 3.6×6.2 arc min at 110.6 MHz and 3.3×5.8 arc min at 123.0 MHz. The 110.6-MHz map is the sum of three nights' observations; two nights' observa-

Table 1 Observed properties of features located near the galactic centre

	110.6-MHz flux density (Jy)	Luminosity (erg s ⁻¹)	α
Northern lobe	65	2×10^{34}	≤-1.0
Jet feature	10	2×10^{33}	≤-0.7
Central compact source	- Marine	2×10^{34}	≈ -0.25

tions are summed at 123.0 MHz. Maps made from each night individually and maps made from data taken before and after transit are all consistent with each other. Observations of sources from the 3C and Culgoora catalogues were used for flux calibration and indicated that ionospheric refraction was not important. Flux densities have been referred to the absolute scale of Baars et al.6.

Figure 1 shows a superposition of the relevant portions of the Clark Lake 110.6- and 123.0-MHz maps on the 160-MHz Culgoora radioheliograph map of Yusef-Zadeh et al.4. The peak of the 160-MHz emission is located at (RA = 17 h 42 min 36.7 s, $dec. = -28^{\circ}58'17''$), which is coincident with the northeastern part of the non-thermal Sgr-A radio shell. The emission extending 10 arc min to the south-east of Sgr-A has been identified as a low-energy jet and is hereafter referred to as the jet feature. Our 123.0-MHz map is in excellent agreement with the Culgoora map and clearly confirms the existence of extended steep-spectrum emission in this region. However, both maps are still dominated by emission from Sgr-A.

At 110.6 MHz the emission from Sgr-A has weakened considerably relative to the emission from the steep-spectrum jet feature lying to the south-east. This is clearly illustrated by the portion of the 110.6-MHz map shown in Fig. 1. This result is partly due to the steep spectrum of the jet feature, and also to the turnover in the spectrum of Sgr-A. (Sgr-A is surrounded by a halo of ionized gas^{7,8} which causes absorption at low frequencies.)

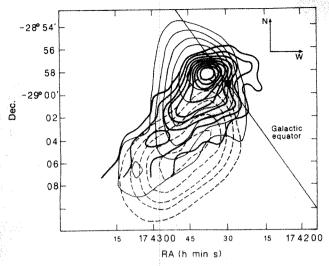

Fig. 1 Contour maps of the galactic centre jet feature. Thick lines, 160-MHz Culgoora map: beam-width, 1.9×1.9 arc min; first contour, 1.2 Jy per beam area; contour interval, 1.2 Jy per beam area. Thin lines, 123-MHz Clark Lake map: beam-width, 3.3×5.8 arc min; peak brightness temperature, 49,193 K; first contour, 19,120 K; contour interval, 5,461 K. Dashed lines, 110.6-MHz Clark Lake map: beam-width, 3.6×6.2 arc min; peak brightness temperature, 10,770 K; first contour, 2,700 K; contour interval, 1,795 K. The black dot indicates the position of the galactic centre (l=0,b=0).

Figures 2 and 3 show the complete 123.0- and 110.6-MHz maps. The three most prominent emission features on the 123.0-MHz map are the continuum arc (G0.16-0.15), the northern galactic centre lobe and Sgr-A. At 110.6 MHz the steep-spectrum jet feature has replaced Sgr-A as a prominent source in the field. The dashed lines on these maps correspond to regions of absorption produced by ionized gas along the line of sight¹.

The 110.6-MHz map (Fig. 3) is important because it reveals the similarities of the northern galactic centre lobe and the jet feature. Both of these objects are extended, steep-spectrum features which are seen only at low frequencies. Moreover, whereas the jet feature appears to be directly linked to the centre, the 110.6-MHz map indicates that the northern lobe extends towards Sgr-A and thus may also be physically connected to the centre. In fact, we would not expect to observe any connection at these frequencies because of the absorption caused by thermal gas in the region between the northern lobe and the centre. The absorption region observed at 110.6 and 80 MHz coincides with a peak in the 55- and 125-µm infrared emission. Unfortunately, the 160-MHz map does not extend far enough north to include the northern lobe.

Recent observations^{10,11} at 10 GHz have also revealed an apparently separate core-lobe system associated with the non-thermal portion of the continuum arc, G0.16-0.15. Evidence for these features is present on our 110.6-MHz maps ('arc lobes'); the observation of these features at low frequencies leaves no doubt as to their non-thermal nature.

Table 1 summarizes the observed properties of the northern galactic centre lobe, the jet feature and the central compact source. We have assumed standard synchrotron source theory. Accurate measurement of the spectral index (α) of the jet feature between 110.6 and 160 MHz is not possible because it depends crucially on the knowledge of the flux contribution from Sgr-A. Also, the spectrum of the jet is subject to significant free-free absorption. We have estimated an upper limit for the spectral index of the jet feature by comparison with higher-frequency maps where this object is not detected. The result of this estimate is $\alpha \le -0.7$, consistent with the estimate by Yusef-Zadeh et al.⁴ of $\alpha \le -0.85$. A new estimate of the spectral index of the northern radio lobe based on the 110.6-MHz map and higher-frequency

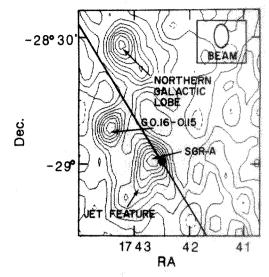

Fig. 2 Contour map at 123 MHz of the galactic centre region: beam-width, 3.3 × 5.8 arc min; peak brightness temperature, 54,600 K; first contour, 2,753 K; contour interval, 5,461 K. Black dot, galactic centre.

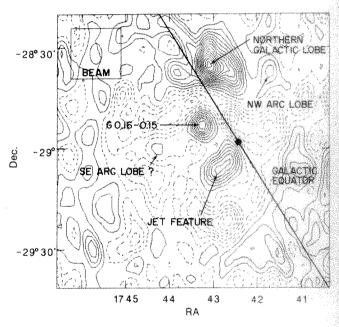

Fig. 3 Contour map at 110.6 MHz of the galactic centre region: field, 1.4° × 1.4°; beam-width, 3.6 × 6.2 arc min; peak brightness temperature, 26,994 K; first contour, 905 K; contour interval, 1,795 K. Black dot, galactic centre.

maps is consistent with the limit of $\alpha \le -1.0$ obtained previously.

We propose that the northern galactic centre lobe and the jet feature have been produced by similar processes associated with the galactic nucleus. In their geometry and other properties, these objects bear a strong resemblance to features observed in the nuclei of Seyfert and active galaxies^{2,12}. These similarities include the spatial scale of the lobes with respect to the central compact source, the fact that the luminosity of these lobes is similar to that of the central compact source, and the fact that the spectra of the lobes are much steeper than that of the central compact source. Similar radio features have been observed in several apparently normal spiral galaxies^{13,14}, substantiating the claim that Seyfert-like activity may be common among spiral galaxies^{15,16}. Asymmetry of these features with respect to Sgr-A

is not surprising. The asymmetrical geometry of these lobes is reminiscent of the 'dog leg' structures observed in several quasars17. These 'dog leg' structures are most probably produced by a collision of the radio lobe with an intergalactic cloud. Given the lower energy of the galactic features and the density of interstellar clouds near the galactic centre, bent radio lobe structures would be probable. Our observations are evidence for activity at the galactic centre driven by physical mechanisms which are similar 18, although scaled down, to those which operate in active galaxies and quasars.

An interstellar line coincident with the P(2,1)transition of hydronium (H₂O⁺)

J. M. Hollis*, E. B. Churchwell†, E. Herbst‡ & F. C. De Luciat

North Carolina 27706, USA

Gas-phase interstellar chemistry is thought to be dominated by ion-molecule reactions. Neutral molecular species abound in the dense interstellar clouds, but only seven molecular ions have been detected. Hydronium (H3O+) is predicted in all ion-molecule reactions¹⁻³ to be an abundant molecular ion, forming OH and H₂O by dissociative electron recombination reactions. Here we report the detection, towards the Orion-KL nebula, of a weak emission spectral line coincident in frequency with the P(2,1) rotation-inversion transition of H₃O⁺. Although we cannot be certain that this single-line detection is H₃O+, we evaluate this possibility with regard to its observed line parameters and, using theoretical chemical models, derive an Orion fractional abundance for H₂O (relative to H₂) of 10⁻⁵ and 10⁻⁶ in thermal and nonthermal cases, respectively. We also report 1-mm-wavelength observations towards Orion which yield new interstellar transitions of CH₃OH, ³⁴SO₂, H₂CS, SO, OCS, SiO and two unidentified lines at 307,313 and 304,374 MHz.

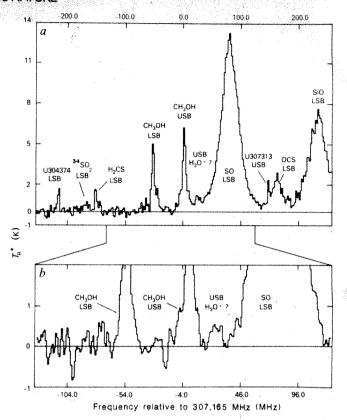

Fig. 1 a, Orion-KL line spectrum at 2 MHz resolution (see Table 1). The abscissa is USB frequency relative to 307,165 MHz, assuming a source $V_{\rm LSR}$ of ± 8.8 km s⁻¹. As this spectrum represents the alignment and averaging of data taken at centre frequencies of both 307,165 and 307,161 MHz, to de-correlate filters, only the USB features are displayed at the correct frequency; the LSB lines are smeared across two channel widths (4 MHz). These data represent 7.1 h of integration time. b, Smoothed version (Hanning smooth) of a portion of the Orion-KL line spectrum at 1 MHz resolution; abscissa as in a. The LSB lines are smeared across four channel widths (4 MHz). These data represent 7.3 h of integration time.

OH and H₂O are well-known and abundant constituents of interstellar clouds, but H₂O does not possess easily observable transitions from which abundances can be determined. In interstellar molecular sources, successful observations of interstellar H₃O⁺ would provide an indirect method of estimating H₂O abundances⁴. Several transitions of the rotation-inversion spectrum of H₃O⁺ have now been measured in the laboratory^{5,6} making possible an interstellar search for this ion. The P(2,1) transition is at a rest frequency of 307,192.41(5) MHz, and the P(3,K) transition with K=0, 1 and 2 lies between 360 and 400 GHz. The upper energy level of the P(2,1) transition is ~105 K above the ground state; this relatively low degree of excitation is seen in other molecular species in molecular clouds such as Orion and SgrB2. Towards the Orion-KL nebula we detected a weak emission feature, coincident in frequency with the P(2,1) transition of H_3O^+ , with line parameters ($T_R^* = 0.6 \text{ K}$, $\Delta V = 10 \text{ km s}^{-1}$, $V_{LSR} = 11 \text{ km s}^{-1}$), which would be consistent with a weak molecular species detected in the 'plateau' or 'doughnut' region of this source7,8.

Although this feature is by no means certain to be attributable to H₃O⁺, we have no other candidate for its identification, and, because of the importance of this species to interstellar chemistry, we are reporting our preliminary observations now and expect that we or others will confirm our present work with further observations of the P(2,1) and the higher-frequency P(3,K) transitions.

Line parameters T_R^* , antenna temperature; ΔV , line-width; V_{LSR} , velocity with respect to the local standard of rest.

The double-sideband observations were made on 12-16 March 1986 with the National Radio Astronomy Observatory (NRAO) 12-m radio telescope. The single-channel, cooled mixer receiver has a single-sideband receiver temperature of ~4,000 K. The sideband separation was 3,000 MHz with a spectrometer consisting of two 256-channel filter banks with 1-MHz and 2-MHz filters. The upper sideband (USB) contained the H₃O⁺ line frequency. Calibration by the chopper method was used to correct for telescope losses and atmospheric extinction. Atmospheric conditions were highly variable, although some stable conditions did occur during observations of Orion and SgrB2. During the stable periods, zenith opacities for Orion observations on 12, 14 and 15 March were 1.1, 1.1 and 0.3, respectively; for SgrB2 on 13, 15 and 16 March they were 0.5, 0.3 and 0.2, respectively. The half-power beam-width was ~21 arc s at 307 GHz. Data were taken while the beam position was switched by 1° in azimuth for SgrB2 and 0.5° for Orion-KL. The antenna temperatures are in terms of T_R* and have not been corrected for beam dilution; we estimate that our calibration scale is correct to within 20%.

Figure 1 shows the H₃O⁺ candidate line at 307,192 MHz at 2 MHz (a) and 1 MHz (b) resolution, along with two unidentified lines and newly detected transitions of several known interstellar species, all of which are reported with line parameters in Table 1. Figure 1 represents a total of more than 7 h of integration time at USB centre frequencies of 307,165 and 307,161 MHz (to de-correlate filters). Complementary integration for 5 h centred on 307,236 MHz showed similar results, and by observing how the spectral lines of the lower sideband (LSB) shifted with respect to the USB centre frequencies, we could identify the sideband of each spectral feature, and thus determine the line rest frequency to within the filter resolution. In all data sets for Orion-KL, the line at 307,192 MHz was evident at $\ge 3\sigma$. The data sets were then frequency-aligned for the USB and averaged, weighted by the integration time and the inverse of the square of the system temperature, to produce the $\geq 5\sigma$ feature shown in Fig. 2 (12 h of integration) at 1 MHz resolution. A similar alignment and averaging for the LSB showed that no LSB spectral feature could account for the USB line at 307,192 MHz. Thus, by these techniques, the reality of the spectral feature at 307,192 MHz was proved.

Assuming that the Orion-KL spectral feature at 307,192 MHz is H₃O⁺, its observed line parameters and calculated transition dipole moment of 1.44 D yield total column densities $N_{\rm T}({\rm H_3O}^+)$ of 7.7×10^{13} and 8.7×10^{13} cm⁻², in the optically thin thermal cases for excitation temperatures of 50 and 90 K, respectively. We point out that the line width may be underestimated due to the weak intensity of the feature, the possible confusion with the nearby CH₃OH line in the USB and the proximity of the SO line in the LSB. Assuming $N_T(H_2) = 3 \times 10^{23} \text{ cm}^{-2}$ for Orion10, a crude estimate of the volume density ratio $n(H_3O^+)/n(H_2) = 2.6 \times 10^{-10}$ and 2.9×10^{-10} can be made for the thermal cases at excitation temperatures of 50 and 90 K, respectively. We estimate a minimum H₂ density of ~106 cm⁻³ for thermalization of the transition to these excitation temperatures. If a density of 105 cm⁻³ characterizes the bulk of the H₃O⁺ emitting region, a far lower excitation temperature (~5 K) prevails for the two levels connected by the P(2,1) transition, although the population in the lower level of this transition is probably thermalized at the temperature of the gas. Under

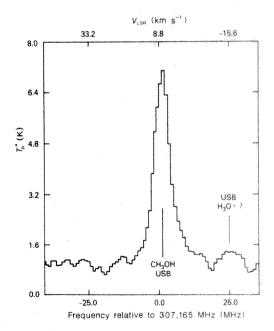

Fig. 2 Hanning smooth spectrum obtained from 12 h of integration towards the Orion-KL nebula with 1 MHz resolution. The lower abscissa is USB frequency relative to 307,165 MHz; the upper abscissa displays the USB velocity scale, assuming a $V_{\rm LSR}$ source velocity of +8.8 km s⁻¹ at a rest frequency of 307,165. The spectrum represents alignment and averaging (see text) of data taken at centre frequencies of 307,161, 307,165 and 307,236 MHz. The CH₃OH line in the USB is blended slightly with a weak H₂CS feature in the LSB for data taken at 307,236 MHz. The -5σ feature labelled H₃O⁺? was apparent in each individual data set at ≥3σ.

[†] Orion-KL J1950.0 position: (05 h 32 min 47 s, -05° 24' 21").

[‡] SgrB2 J1950.0 position: (17 h 44 min 11s, -28° 22′ 30″). § The 4_1-4_0 A transition of 13 CH₃OH is calculated to be 307,311.4 (20) MHz; laboratory measurements are pending.

these conditions, for the non-thermal case we obtain $n(H_3O^+)$ / $n(H_2) = 2.3 \times 10^{-9}$ and 2.8×10^{-9} for gas temperatures of 50 and 90 K, respectively. Our thermal and non-thermal sets of fractional abundances are in reasonable agreement with ion-molecule models, which yield 10^{-11} - 10^{-9} , depending on cloud age, gas density and elemental depletion2. We have assumed that the volume density ratio can be estimated by the column density ratio. This is not strictly true where fractional abundances change and line saturation effects occur along the line of sight. However, our order-of-magnitude estimate indicates that the spectral feature at 307,192 MHz is roughly consistent with H₃O⁺ abundances in present chemical models for Orion-like interstellar clouds.

The estimated fractional abundance of H₃O⁺ can be used to determine the fractional abundance of gas-phase H₂O by considering a limited set of ion-molecule reactions⁴. Assuming a rate coefficient of 6×10^{-6} cm³ s⁻¹ for the dissociative recombination reaction of H₃O⁺, a branching ratio of 0.5 to form H₂O+H (ref. 11), rate coefficients of $\sim 10^{-8}$ cm³ s⁻¹ for the destruction of H₂O by ion-molecule reactions¹², and a value of 0.1 for the ratio of the total abundance of reactive ions to the electron abundance, we obtain fractional abundances for H2O in Orion of 10^{-5} and 10^{-6} for the non-thermal and thermal cases, respectively.

We thank Mr John Payne, NRAO engineer, for providing a working 307-GHz receiver system on very short notice; Mr Ray

Lichtenhahn and Mr Calvin Sparks for assisting with the observations; and Dr Philip Jewell for advice concerning execution of the observations and publication of results. F. C. De L. and E. H. acknowledge the support of NASA grant NAGW-189. NRAO is operated by Associated Universities. Inc., under contract with NSF.

Note added in proof: Independent confirmation of our Orion-KL results was provided by H. A. Wootten (NRAO) and coworkers during 17-21 March 1986. Our laboratory measurements reveal a weak, unassigned (presumably high-excitation) line of CH₃OH at 307,193.27 (5) MHz, which we doubt could account for our Orion-KL line labelled 'H3O+?', due to linewidth, velocity and intensity arguments.

Impact-induced atmospheres and oceans on Earth and Venus

Takafumi Matsui* & Yutaka Abe

Geophysical Institute, Faculty of Science, University of Tokyo, Bunkyo-ku, Tokyo 113, Japan

High-velocity impacts of planetesimals onto a growing planet result in the impact-degassing of volatiles and the formation of an impact-induced atmosphere. Because of the blanketing effect of such an atmosphere, it is likely that the surface of the proto-Venus melted once the radius exceeded ~40% of the final radius. The final mass of H₂O in the impact-generated atmosphere, predicted to be $\sim 10^{21}$ kg on the basis of thermal evolution models of the growing proto-Venus, does not depend on the initial water content of the Venus-forming planetesimals and is almost identical to the present mass of the Earth's oceans. We show here that an impact-induced H₂O atmosphere of ~10²¹ kg mass probably formed on both Venus and Earth during accretion, but that whereas H₂O in the proto-atmosphere of the Earth could condense to form a hot (~600 K) ocean, such condensation probably did not occur on Venus.

Recent studies^{1,2} have suggested that an impact-induced atmosphere increases the surface temperature of the Earth to a stage where a magma ocean is possible, and that the total mass of H₂O in an impact-induced atmosphere clusters around 10²¹ kg, a value which is rather insensitive to variations in the input data. As the accretion of planetesimals is fundamental to the process of planetary formation, development of an impactgenerated atmosphere during accretion may have occurred on other terrestrial planets. In particular, the early evolution of Venus might be expected to be similar to that of the Earth, because the two planets are of similar size and mass and were formed at comparable distances from the Sun. Why then have Venus and Earth experienced different histories?

Assuming that Venus-forming planetesimals contained H₂O in amounts similar to those retained in Earth-forming planetesimals, we can calculate the evolution of an impactinduced H₂O atmosphere during accretion (see ref. 2 for details of the calculation). Figure 1 shows the atmospheric evolution during accretion for two Venus models. The accretion times, $\tau_{\rm acc}$, are assumed to be 1.6×10^7 yr, which is about one-third of $au_{\rm acc}$ of the standard Earth model. The degassing parameter and critical pressure for impact dehydration are 0.2 and 2.28× 10¹⁰ Pa, respectively. The solid and dash-dot curves represent the results of the standard model (initial water content of planetesimals $X_w = 0.1\%$) and higher water content model $(X_w = 1\%)$, respectively. As shown in Fig. 1, the final amount of H₂O in the atmosphere does not differ greatly between these two models and is $\sim 10^{21}$ kg. This amount does not vary significantly with changes in $X_{
m w}$ and $au_{
m acc}$ for $0.03 < X_{
m w}(\%) < 1$ and $10^6 < \tau_{\rm acc}(yr) < 10^8$ (ref. 2). This is because the solubility of water in silicate melt controls the amount of H₂O in the proto-atmosphere. Note that the final amount of H₂O in the atmosphere is almost identical to the amount presently found in the Earth's oceans (1.4×10²¹ kg). These are the same features which we found in our model for the Earth2. Therefore, we can reasonably consider that both planets originally had proto-atmospheres of similar mass, composed primarily of H2O. An initial mass of atmospheric water equal to the mass of the terrestrial oceans is also consistent with the present deuterium-to-hydrogen ratio on Venus³.

Given the apparent similarity of the initial atmospheric conditions on Venus and the Earth, it is interesting to study the divergence which subsequently took place in the development of the atmospheres of these two planets. The qualitative nature of the evolution of an impact-generated atmosphere can be inferred simply from its radiative equilibrium thermal structure. The main heat source of such a proto-atmosphere is the impact energy released during accretion. In this case, the atmosphere is heated from below, and thus its thermal structure is determined by the opacity of the atmosphere to infrared radiation (that is, by the blanketing effect). The solar flux supplants the impact energy flux as the main heat source of the atmosphere when its formation is complete, as the Safronov-type accretion rate assumed in this study² decreases rapidly as the final radius is

Present address: Department of Earth, Atmospheric, and Planetary Sciences, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA.

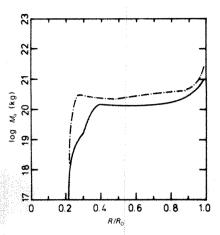

Fig. 1 Total mass M_a of the impact-generated H_2O atmosphere on Venus, plotted against normalized radius for the standard (solid curve) and higher water content (dash-dot curve) models. Note that the final mass of H_2O in the atmosphere is similar to the present mass of the Earth's oceans (10^{21} kg).

approached. When the atmosphere is heated primarily by solar radiation, its thermal structure is determined by the so-called greenhouse effect, which depends on the opacity of the atmosphere not only to long-wave (infrared) radiation, but also to short-wave (visible) radiation. This is because only the solar radiation that is able to penetrate the atmosphere can serve as a heat source. The difference between the blanketing effect and the greenhouse effect is small for a thin atmosphere, because most of the received solar radiation penetrates the atmosphere and heats it from below. For the case of a thick atmosphere, however, most of the solar radiation does not penetrate the atmosphere, as it is scattered and/or absorbed.

We can obtain the temperature profile of a plane parallel atmosphere in radiative equilibrium by solving the equations: $dF_u/d\tau = F_u - \pi B$, $df_u/dt = f_u - \omega (f_u + f_d)/2$, $dF_d/d\tau = -F_d + \pi B$, $df_d/dt = -f_d + \omega (f_u + f_d)/2$ and $F_u - F_d + f_u - f_d = F_0$, with the boundary conditions: $F_u = (1 - A)S_0/4 + F_0$, $f_u = AS_0/4$, $f_d = S_0/4$ and $F_d = 0$ at the top of the atmosphere ($\tau = 0$ and t=0), and $F_{\rm u}=\sigma T_{\rm s}^4$ and $f_{\rm u}=\mu f_{\rm d}$ at the base of the atmosphere $(\tau=\tau_{\rm s} \text{ and } t=t_{\rm s})$. Here, F and f are the long- and short-wave radiation fluxes, τ and t are the normal optical depths for the long- and short-wave radiation fluxes, B is the Planck function, ω is the albedo for single scattering, σ is the Stefan-Boltzmann constant, F_0 is the thermal energy flux given at the base of the atmosphere, S_0 is the solar flux, A is the planetary albedo, T_s is the temperature at the base of the atmosphere, and μ is the reflectivity of the short-wave radiation at the bottom of the atmosphere. The subscripts u and d denote upward and downward radiation, respectively. For a grey atmosphere, $\pi B = \sigma T^4$, where T is the temperature. To derive the above equations, we assumed local thermodynamic equilibrium for long-wave radiation and isotropic scattering for short-wave radiation, and we used a two-stream approximation. Assuming that $\lambda = \tau/t$ and ω is constant, the solutions are given by

$$\alpha T^4 = F_0 \frac{\tau + 1}{2} + \frac{S_0}{4} \frac{(\lambda + \alpha) + (\lambda - \alpha)\beta + (\alpha^2/\lambda - \lambda)(e^{-\alpha t} + \beta e^{\alpha t})}{(1 + \alpha) + (1 - \alpha)\beta}$$

$$\sigma T_s^4 = F_0 \frac{\tau_s + 2}{2} + \frac{S_0}{4} \frac{[(\lambda + \alpha) - (\lambda - \alpha) e^{-\alpha t_s}](1 - \beta_0 e^{\alpha t_s})}{(1 + \alpha) + (1 - \alpha)\beta}$$

where $\alpha = \sqrt{(1-\omega)}$, $\beta = \beta_0 e^{-2\alpha t}$, and $\beta_0 = [\mu(1+\alpha) - (1-\alpha)]/[(1+\alpha) - \mu(1-\alpha)]$.

Figure 2 shows the radiative equilibrium thermal structures of the proto-atmospheres of Venus and the Earth, as determined from the above equations. As mentioned previously, the radia-

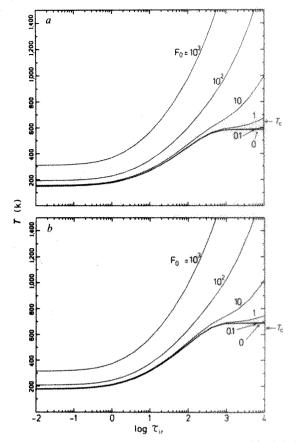

Fig. 2 The radiative equilibrium thermal structures of the proto- $\rm H_2O$ atmospheres for: a, the Earth, $S_0 = 960~\rm W~m^{-2}$; b, Venus, $S_0 = 1,830~\rm W~m^{-2}$. S_0 is the solar flux (we used a value 30% less than the present value), and F_0 is the energy flux released at the surface of a planet (in W m⁻²). $\tau_{\rm ir}$ is the optical depth of the atmosphere to infrared radiation. Note that with a decrease in F_0 the temperature at the base of the Earth's atmosphere becomes lower than the critical temperature T_c for H_2O to liquefy at a pressure of $\sim 100~\rm bar$.

tive equilibrium structure depends mainly on the ratio λ of the optical depths of infrared (long-wave) and visible (short-wave) radiation. Although it is difficult to estimate this ratio theoretically and/or experimentally, we may infer it from Pioneer-Venus data on the absorptional features of the venusian atmosphere*, where surface pressure is $\sim \frac{1}{4}$ or $\frac{1}{5}$ that of the proto- H_2O atmosphere. The planetary albedo and the net solar radiation flux f_a at the surface are given by $A = [(1-\alpha) + \beta_0(1+\alpha)\varepsilon^2]/[(1+\alpha) + \beta_0(1+\alpha)\varepsilon^2]$ $\beta_0(1-\alpha)\varepsilon^2$ and $f_s = \alpha S_0(1-\beta_0)\varepsilon/2[(1+\alpha)+(1-\alpha)\beta_0\varepsilon^2],$ where $\varepsilon = \exp(-\alpha t_s)$. Using the observed values of A (0.77), f_s/S_0 (0.005), S_0 (2,620 W m⁻²), T_s (750 K) and μ (0.1) for the present venusian atmosphere⁴, we can determine $\omega = 0.98$ and $\lambda = 31$ from the above equations (ω and λ are almost independent of μ). As the pressure effect on the absorption features of the atmosphere may not change significantly with wavelength, the ratio λ is expected to be insensitive to variations of pressure. The temperature effect on the absorptional features is also small, for temperature variations on the order of several hundred degrees. Therefore, we may consider $10 < \lambda < 100$ for the H_2O proto-atmosphere. In this respect, the following results are insensitive to this ratio. For both planets, the equilibrium thermal structure shifts to a lower level as the impact energy rate decreases. As the impact energy rate approaches zero (greenhouse case), the equilibrium thermal structure for the Earth falls below the vapour pressure, which means that the H₂O in the Earth's proto-atmosphere can condense to a liquid. The equilibrium thermal structure for Venus, however, remains higher than the vapour pressure. It is therefore possible that the H₂O

in the Earth's proto-atmosphere condensed to form oceans. while in the proto-venusian atmosphere it remained in gaseous form. Studies of the escape of H₂O from the proto-venusian atmosphere (see ref. 5) suggest that the H₂O in the protovenusian atmosphere may have disintegrated into hydrogen and oxygen through photodissociation, with the resulting H2 subsequently escaping through a hydrodynamic process⁵.

Figure 2 shows that the temperature of the first rain on Earth was ~600 K, and thus a hot proto-ocean may have resulted. The mean temperature of this ocean has been estimated from measurements of the oxygen isotope composition of metamorphosed sedimentary rock. According to Oskvarek and Perry⁶, the mean temperature of the early Archaean ocean may have been as high as 420 K. Our result is consistent with this observation. Sagan and Mullen noted that the surface temperature of the proto-Earth would have been too cold for water to be liquid if the atmosphere had the same composition as at present; they argued for the existence of a reduced atmosphere, which would lead to warmer conditions on the proto-Earth. Our model, in contrast, does not require such an ad hoc assumption. We speculate that the interactive evolution of the hot proto-atmosphere, proto-ocean and proto-crust may have played an important role in the origin of the continents on the Earth; this topic deserves further study.

We thank S. C. Solomon for comments and Jan Nattier-Barbaro for assistance in manuscript preparation. This study was partially supported by grants-in-aid for scientific research from the Ministry of Education of Japan (60540247 and 59390007) and, in the final stage of preparation at MIT, by NASA grant NSG-7297.

The quasi-crystalline phase in the Mg-Al-Zn system

T. Rajasekharan, D. Akhtar, R. Gopalan & K. Muraleedharan

Defence Metallurgical Research Laboratory, Hyderabad-500 258, India

Shechtman et al.1 have reported a phase in rapidly solidified Al86Mn14 alloy with long-range orientational order, but with icosahedral point-group symmetry, which is inconsistent with lattice translations. However, Pauling² has argued that the apparent icosahedral symmetry in Al86Mn14 alloy is due to directed multiple twinning of cubic crystals with a cube edge of 26.7 Å. We report here the powder X-ray diffraction study of a rapidly solidified Mg₃₂(Al, Zn)₄₉ alloy which shows 5-3-2 symmetry diffraction in transmission electron microscopy (TEM). Also reported is a study of rapidly solidified Mg2Al3 alloy. The advantage of these alloys is that B-Mg2Al3, which has nearly the same structure as proposed by Pauling for the rapidly quenched Al₈₆Mn₁₄, is an equilibrium phase. This is unlike the Al-Mn system, where, according to Pauling, the cubic phase occurs in a metastable and already twinned form. The present choice of alloy systems makes it possible to compare the X-ray diffraction patterns from the quasi-crystalline phase and a cubic phase with nearly the same structure as proposed by Pauling. We observe that the X-ray diffraction pattern of rapidly

solidified Mg32(Al, Zn)49 alloy is distinct from those of the equilibrium phases and that the pattern can be completely indexed to an icosahedral phase. We argue that the above observation is inconsistent with the proposal that the material consists of an aggregate of twinned cubic crystals. Therefore, the alternative is to invoke a quasi-crystalline lattice to explain the observed 5-3-2 symmetry diffraction in TEM.

Although selected area electron diffraction patterns (SADP) displaying 5-fold, 3-fold and 2-fold axes can be explained by multiple twinning of cubic crystals³, Shechtman et al. argued that their phase shows long-range orientational order with icosahedral point-group symmetry because the dark-field images taken from any reflection had the entire grain illuminated. Also, micro-diffraction from many different volume elements of a grain (each with an area of ~200 Å²) displayed all reflections in the SADPs. However, their contention in support of the absence of microtwinning, that the X-ray diffraction pattern of rapidly quenched Al₈₆Mn₁₄ alloy cannot be indexed to any Bravais lattice, has been re-examined by Pauling², after including the unindexed lines in a pattern obtained from Schechtman.

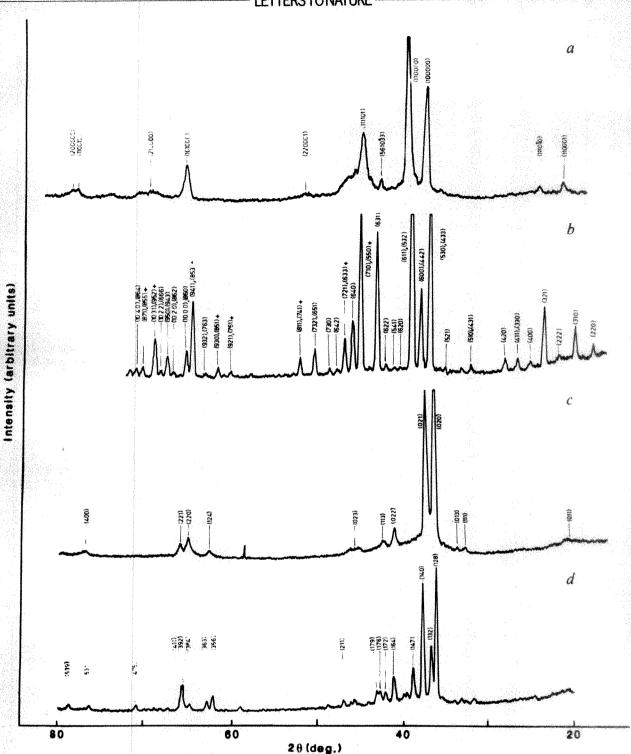

Fig. 1 X-ray diffraction pattern (CuK α radiation) from: a, rapidly quenched Mg₃₂(Al, Zn)₄₉, indexed to an icosahedral phase (see text); b, rapidly quenched Mg₃₂(Al, Zn)₄₉ after transformation (cI162, a=14.16 Å); c, rapidly quenched Mg₂Al₃ (hexagonal with a=5.73 Å, c=9.54 Å); and d, rapidly quenched Mg₂Al₃ after transformation (cF1192, a=28.28 Å).

Pauling re-indexed the entire pattern to a cubic cell with an edge of 26.7 Å. However, because the proposed cubic cell is large and intensity calculations have not been made, the accuracy of the indexing proposed by Pauling is highly dependent on the reliability of his model for the contents of the unit cell.

Pauling proposed a model in which a molten alloy of $Al_{86}Mn_{14}$, on sudden cooling, could form metastable cubic crystals of cube edge ~ 26.7 Å, with the unit cube containing $\sim 1,120$ atoms; and that these crystals would show ordered multiple growth such that 20 of them grow out from a central seed to

produce an aggregate with icosahedral symmetry. The arrangement of the atoms in the unit cell is similar to that in the unit cell of rare-gas hydrates. β -Mg₂Al₃, which is cubic with cube edge 28.24 Å and 1,192 atoms per cell, has essentially the same structure² as the metastable cubic phase.

In this context, the X-ray diffraction pattern from rapidly quenched Mg₃₂(Al, Zn)₄₉ alloy, which gives 5-3-2 symmetry diffraction patterns in TEM⁴, is of interest. We prepared the alloys Mg₃₂(Al, Zn)₄₉ (with Al and Zn in the ratio 1:2) and Mg₂Al₃ from the pure elements (better than 99.9% in all cases) by r.f. induction melting over a water-cooled copper hearth. The

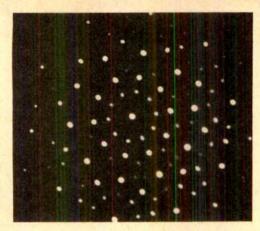

Fig. 2 Selected area diffraction pattern from a typical grain of rapidly solidified Mg32(Al, Zn)49 alloy displaying 5-fold symmetry.

alloys were re-melted in quartz nozzles and rapidly solidified into thin ribbons by ejecting onto a rotating copper wheel under argon cover. The quenched ribbons were thinned by electropolishing and were examined by TEM. X-ray diffraction patterns were obtained using a Siemens diffractometer with CuKa radiation.

The X-ray diffraction patterns from rapidly quenched Mg₃₂(Al, Zn)₄₉ and Mg₂Al₃ are shown in Figs 1a and c, respectively. Although there is an apparent similarity in these patterns, the latter could be indexed completely to a hexagonal unit cell with a = 5.73 Å, c = 9.54 Å (see Table 1), and its SADPs revealed no axis with 5-fold symmetry. In the case of rapidly quenched Mg₃₂(Al, Zn)₄₉ alloy, the TEM patterns showed 5-3-2 symmetry. The SADP along a 5-fold axis is shown in Fig. 2. The X-ray pattern in Fig. 1a could be completely indexed, following Bancel et al.5, using the 12 vectors pointing to the vertices of an icosahedron, which are generated by cyclic permutation of $(q_x, q_y, q_z) = (\pm 1, \pm \tau, 0)$. The six independent vectors chosen are $q_1 = (1, \tau, 0), q_2 = (1, -\tau, 0), q_3 = (0, 1, \tau), q_4 = (0, 1, -\tau), q_5 =$ $(\tau, 0, 1), q_6 = (-\tau, 0, 1),$ where τ is the golden mean, $(1+\sqrt{5})/2$. The observed d-spacings and the icosahedral indices are given in Table 2.

Differential scanning calorimetric (DSC) scans of asquenched Mg32(Al, Zn)49 and Mg2Al3 showed well-defined exotherms with peak temperatures of 613 and 568 K, respectively (Fig. 3). The ribbons were annealed at temperatures beyond the exotherms for 15 min in the DSC cell in argon atmosphere. The annealed specimens showed no axis with 5-fold symmetry in TEM.

X-ray diffraction patterns were obtained from the annealed specimens in identical conditions as for the as-quenched alloys. The patterns obtained from annealed Mg₃₂(Al, Zn)₄₉ and Mg₂Al₃ are shown in Fig. 1b and d, respectively. The former can be indexed to the equilibrium cubic phase (cI162, a = 14.16 Å; ref. 6) and the latter to β -Mg₂Al₃ (cF1192, a = 28.3 Å; ref. 7).

A comparison of the diffractograms in Fig. 1a, b, for the rapidly quenched and annealed Mg32(Al, Zn)49 alloy, respectively, suggests that if we were to assume that the 5-fold symmetry in TEM results from 20 cubic crystals with definite angular relationships in their orientations, the obvious choice for the cubic unit cell will be the c1162 type. The reason for this is that

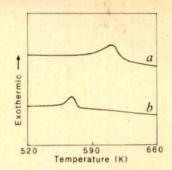

Fig. 3 DSC thermograms from rapidly quenched Mg₃₂(Al, Zn)₄₉ (a) and Mg2Al3 (b).

the major lines in Fig. 1b coincide with the lines in Fig. 1a. The rapidly quenched Mg32(Al, Zn)49 alloy shows a distinct transformation temperature in DSC. This transformation could be a crystal structure change or an irreversible change in which the cubic crystals lose their mutal angular relationships. However, only a crystal structure change can be expected to cause a substantial change in the X-ray powder diffraction patterns. The X-ray diffraction pattern in Fig. 1b shows many intense lines which are missing altogether in Fig. 1a. Therefore, the exotherm in the DSC thermogram does not correspond to a transformation in which the mutual angular relationships between the cubic crystals are destroyed. As most of the lines in Fig. 1a have d-spacings in common with those in Fig. 1b, the question of texture in the as-quenched ribbons also arises. However, a comparison of diffractograms obtained from the strips and a fine powder made from the strips ruled out texture in the as-quenched ribbons as a cause for there being relatively fewer lines in Fig. 1a. Note also that the diffraction pattern in Fig. 1a is not similar to that of β-Mg₂Al₃ in Fig. 1d.

Thus, the rapidly quenched Mg32(Al, Zn)49 alloy does not consist of aggregates of cubic crystals of either type, cI162 or cF1192. The X-ray pattern is completely indexable to an icosahedral phase. Hence, a quasi-crystalline lattice is necessary to explain the observed 5-3-2 symmetry diffraction in TEM.

Pauling (personal communication) has suggested that the pattern given in Fig. 1a can be indexed to a disordered NaCd2type structure with a = 27.82 Å (cF1120), and that on annealing there are changes in the structure such as to eliminate all or most of the randomness. However, it is not clear as to how, on annealing, the material transforms to a cI162-type structure rather than to an ordered form of NaCd2-type structure. The indexing of the pattern in Fig. 1a to a disordered NaCd2-type structure is not necessarily unique. One could also assign the pattern to a cI162-type phase with disorder in the unit cell, as the major lines in Fig. 1b coincide with the lines in Fig. 1a. However, there has been no report of a disordered Mg32(Al, Zn)49-type structure. The equilibrium Mg32(Al, Zn)49 phase has a unit cell in which spherical aggregates of atoms which basically have 5-3-2 symmetry are packed in bodycentred cubic lattice positions. The question of whether disorder in such a lattice would lead to a quasi-crystalline structure, yielding the X-ray diffraction pattern shown in Fig. 1a, becomes interesting.

We thank Professor P. Rama Rao for critical discussions and permission to publish this letter.

High-resolution transmission electron microscopy of silicon re-growth at controlled elevated temperatures

R. Sinclair & M. A. Parker

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305, USA

Direct observations of atomic surface rearrangements and dislocation reactions using high-resolution transmission electron microscope (TEM) techniques have been described for gold and for cadmium telluride1-6. A major disadvantage of these experiments has been that they rely on the heating effect of the imaging electron beam to raise the temperature of the sample so that thermally activated processes can be induced. This severely restricts the materials which can be studied and significantly reduces the control of the observer in bringing about changes of interest. We have previously suggested4 that many solids would be open to such investigation if an appropriate temperature range could be reached. Using a simple Arrhenius kinetic law, we estimated, for example, that silicon would need to be held at ~600 °C to make equivalent observations to those seen in CdTe. Recognizing the contemporary technological applications of silicon, such a step would be important in fundamental studies of device circuits. We report here that this type of imaging can indeed be performed successfully, without recourse to specialized instrumentation, and that new insights can be gained concerning defect production and phase transformations in this important material.

The experiment involved the observation of silicon re-growth in situ in a TEM at temperatures between 500 and 800 °C. A silicon thin film (300 nm) had been epitaxially deposited on a sapphire substrate and had undergone a dual ion-implant and annealing treatment. The implants have the effect of rendering the highly defective silicon crystal amorphous, while the annealing produces a virtually defect-free single-crystal film. We investigated this latter reaction (the amorphous to crystalline transformation) during solid-phase epitaxial re-growth.

Samples were made for TEM using a standard cross-sectioning technique⁸, which allowed high-resolution electron microscope (HREM) imaging in the standard [110] orientation. The electron microscope was a conventional Philips EM400 ST operating at 120 kV, with a resolution of ~0.32 nm. Heating was achieved with the standard, commercially available holder (model number PW 6592), in which an electrical feed-through heats a platinum pad on which was placed the 3-mm disk specimen. The temperature is measured by a thermocouple attached to the pad. Because of the high thermal conductivities of sapphire and silicon, the thermocouple reading should be

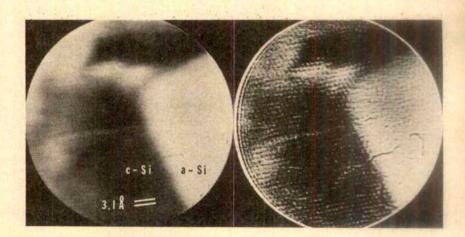

reasonably close to the actual specimen temperature. Care was taken to use reproducible imaging conditions so that any beamheating or other effects would give rise to a systematic error in the apparent temperature.

One of the most important experimental parameters for the HREM is the specimen orientation with respect to the imaging electron beam. As the present holder has only single-tilting capability, the external configuration must be used to facilitate orientation control. The surface normal of the silicon film is [100]. In a cross-section specimen, the thin film is easily seen as a line across the middle of the disk. When this line is oriented perpendicular to the holder rod, the tilt axis is then accurately the [100] crystal direction. Appropriate sectioning therefore allows attainment of the desired orientation. Axial crystal lattice images were produced using the transmitted and six diffracted beams. A Philips plumbicon image pick-up system (model number PW 6326/50), coupled to a standard video recorder and television monitor, was used to display and record the pictures. Subsequent image processing was carried out with a Quantex QX-9000 digital image processing and analaysis system; additional details are given elsewhere9. Starting from room temperature, it takes ~1 h for the image drift to stabilize sufficiently for reasonable HREM observations to be obtained at ~700 °C. The thermocouple reading can be maintained to within ±5 °C over several hours, and this is confirmed by the stability of the image itself. Controlled temperature changes can be effected, although a few minutes are required for re-stabilization.

Figure 1 shows a region of the crystalline/amorphous silicon interface. A photograph taken from continuous play-back of the video recording (Fig. 1a) is compared with the digitally enhanced image (Fig. 1b). The former image is of lower quality then conventional HREM images photographically recorded at room temperature; however, the processed image is adequate for standard image interpretation. Detailed studies of the kinetics of the crystallization process as a function of temperature yielded a variation and an activation energy consistent with those found by two alternative techniques, indicating that the same mechanism is operative 10. Our data show a small systematic displacement from the others which may arise either from an error of ~40 °C in the apparent temperature or from an influence of the TEM thin foil on the reaction rate.

Crystallization is observed to occur by the gradual advance of the crystalline/amorphous interface; there is no detectable crystal nucleation ahead of this interface. Faceting on low-index planes is common, particularly on {100} (which is the broad face of the epitaxial growth) and {111}. The latter give rise to protrusions, or recessions, of the growth front, as shown in Fig. 1. One peculiarity, which cannot be detected by bulk investigative techniques, is that occasionally the interface would advance over several atomic distances apparently instantaneously (that is, between two successive 1/30 s video frames). Thus, a large

Fig. 1 Comparison of video-recorded lattice images of the amorphous/crystalline silicon interface at 720 °C: a, 1-s exposure photograph during play-back of the video-tape; b, photograph of the image after digital filtering and eight-frame averaging.

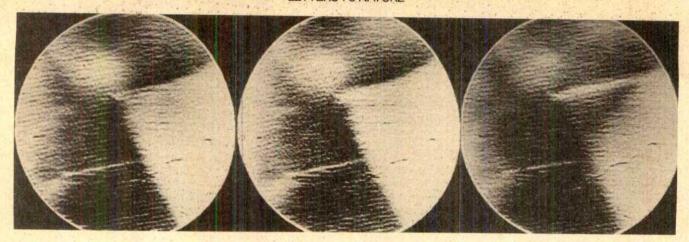

Fig. 2 Sequence of micrographs at 720 °C, taken 1 s apart, showing sudden crystallization of many atoms, advancing the crystalline/amorphous interface. Frame-by-frame analysis shows that the event occurs between two successive frames, 1/30 s apart.

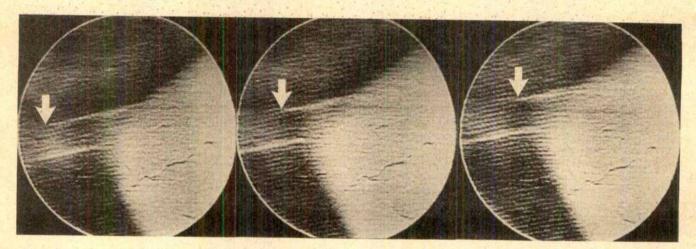

Fig. 3 Sequence of micrographs at 720 °C, taken 10 s apart, showing the gradual motion of a Shockley partial dislocation (arrowed) towards the amorphous/crystalline interface, annihilating a stacking fault in the process. This sequence is similar to that observed previously in CdTe (refs 5, 6).

number of atoms, in some cases >10⁴, extend the epitaxial crystal spontaneously. This suggests that under certain conditions the mechanism of crystallization occurs by something other than a simple atom-by-atom process, and that the silicon tetrahedral network can be created perfectly with much coordination of the atomic rearrangement. Such cooperative phenomena would be expected in a heterogeneous nucleation event. This behaviour is illustrated by the sequence shown in Fig. 2, from growth at a measured temperature of 720 °C.

Also unexpected was the observation that the interface sometimes regresses. This can be explained if we invoke the influence of interfacial stresses (arising from the volume change of the transformation), as well as the influence of interfacial surface energies for the differing crystallographic orientations, as playing some part in the behaviour. We speculate that these videorecordings of the regressions and advances of the interface are the first direct record, at near-atomic resolution, of the fluctuations expected from transition-state theory between a metastable and a stable phase. The presence of oxygen and aluminium (from the sapphire), as well as the thinness of this particular region, may also have some influence on the fluctuations.

Lattice imperfections can also be created at the interphase interface, which lends credence to the idea that significant stresses are present, particularly at 'corners' like that shown here. Shockley partial dislocations can be ejected, passing along a {111}-type slip plane and resulting in an intrinsic stacking fault. More complex dislocation reactions can occur which can be analysed in detail by Burgers circuits drawn around the

dislocation cores at various stages of the reaction. Although we observed several different events, the image quality was not sufficiently good for the analysis to be carried out with real certainty in all cases. However, this should not be a problem with the new generation of high-resolution TEMs now available. Figure 3 shows a sequence in which a Shockley partial is approaching the interface and recreating the perfect crystal, an observation identical to that made in cadmium telluride, described previously^{5,6}. One has the impression that the interface region is unstable, and that unusual events can occur at any instant. Furthermore, although stacking faults in many materials are thought to arise from accidents of growth, we see here that they are directly created by a dislocation mechanism.

We have been successful in obtaining lattice-resolution micrographs and continuous recordings at controlled elevated temperatures, using a conventional TEM and heating stage. We have studied crystallization and defect reactions in silicon at a temperature (~700 °C) similar to that referred to in our original predictions⁴ (that atomic rearrangements would occur in silicon at ~600 °C), and the phenomena are exactly analogous to those observed in CdTe using beam heating^{5,6}. Therefore, it is reasonable to conclude that atomic-level events of this type, including phase transformation processes, may be investigated in detail in many materials, at the appropriate temperature.

A new type of host compound consisting of α -zirconium phosphate and an aminated cyclodextrin

Tsuyoshi Kijima* & Yoshihisa Matsui†

- * National Institute for Research in Inorganic Materials, Sakura-mura, Niihari-gun, Ibaraki, 305 Japan
- † Department of Agricultural Chemistry, Shimane University, Nishikawazu, Matsue, 690 Japan

Pillaring of layered compounds by polynuclear hydroxy metal cations or bulky organic species has been applied to the formation of microporous networks analogous to zeolites1.2. Similar types of compound may be obtained by the intercalation of host molecules such as cyclodextrins in layered parent hosts. Our previous work^{3,4} first demonstrated such a combined host compound, in which molecules of mono-(6-β-aminoethylamino-6-deoxy)-β-cyclodextrin (CDen) are intercalated as a bi-layer with their cavity axes perpendicular to the silicate layers of Cu(II)-montmorillonite. We have now prepared a complex of layered α -zirconium phosphate with CDen, in which the CDen molecules are arranged as a bi-layer but with their cavity axes parallel to the inorganic layers. The dextrin moiety of the present complex also appears to possess a zeolitic character.

Cyclodextrins contain a cylindrical cavity capable of including a variety of molecules, together with catalytically active hydroxyl groups. The cyclic dextrins and their derivatives therefore serve as micro-encapsulating agents for drugs or as models of enzymes⁵. Zirconium phosphate is an inorganic ion exchanger with a layered structure and acts as an intercalating agent for polar organic substances⁶. The crystalline phase with composition Zr(PO₄)₂·H₂O has an inter-layer spacing of 7.6 Å and is called α -zirconium phosphate (α -ZrP).

The α -ZrP sample was the same as that used previously⁷; the CDen was prepared as described in refs 3, 4. Crude CDen was purified by chromatography, using a carboxymethyl cellulose column with 0.1 M ammonium bicarbonate as an eluant, followed by repeated evaporation of the cluate in the presence of a small amount of ammonia. The phosphate sample was soaked in an aqueous solution containing varying amounts of CDen at 25 °C for 14 days, centrifuged, fully washed with water, and air-dried at 40 °C.

Figure 1 shows the X-ray diffraction patterns of the resulting solids. As a result of the addition of CDen, the peak at d = 7.6 Åattributable to the (002) reflection of α -ZrP decreased considerably in intensity, while a new diffraction peak (C(001)) appeared at d = 35.6 Å along with its higher-order counterparts. This indicates that the \alpha-ZrP phase is directly converted into its CDen complex with an inter-layer spacing of 35.6 Å. This con-

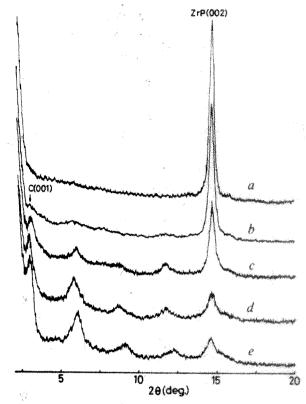

Fig. 1 X-ray diffraction patterns of α -zirconium phosphate (a) and its complexes with CDen (FeKa radiation). CDen addition levels (mmol g⁻¹): 0.43 (b), 1.3 (c), 2.3 (d) and 5.2 (e).

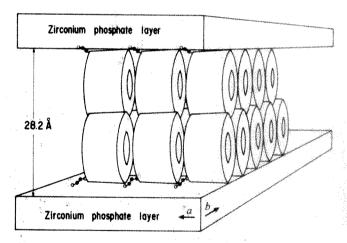

Fig. 2 Model proposed for the packing of CDen molecules in the inter-layer space of α -zirconium phosphate. Directions a and brefer to the axes of the α -ZrP unit cell (see Fig. 3).

version proceeded with increasing amounts of CDen until, at a level of 5.2 mmol CDen per g α -ZrP, the rate of conversion ξ amounted to 88%, according to a rough estimate based on the peak area of the (002) reflection for the residual phosphate phase. The amounts of CDen and water, x and y, per formula weight of α -ZrP for the solid obtained at this highest level of CDen addition (sample A) were determined to be 0.368 and

5.3 mol, respectively, by thermo-gravimetric analysis.

Similarly to basic amino acids, CDen is likely to be intercalated by α -ZrP in such a way that the inter-layer surface protons are replaced by the terminal NH₃⁺ cations. The thickness of the intercalated layer, Δ , for the resulting CDen-ZrP complex is estimated as 28.2 Å by subtracting 7.4 Å for the thickness of the inorganic layer from the observed inter-layer spacing. It is therefore reasonable to assume that CDen molecules, each 15.4 Å in

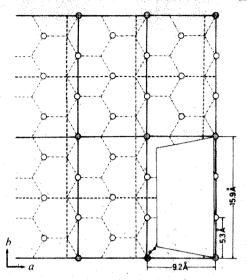

Fig. 3 An idealized relationship between the arrangements of the POH groups and CDen molecules in the inter-layer space of α -zirconium phosphate (projection on the a-b plane). The upward-pointing POH groups in the lower layer are represented by circles and the downward-pointing ones in the upper layer are located at the triple points of dash-dot lines. Each CDen molecule with its cavity axis parallel to the a axis anchors through the basic terminus to the POH site (shaded for the lower layer) and is placed in the rectangle surrounded by the solid (lower layer) or broken (upper layer) lines.

diameter and 8.0 Å in the thickness of the torus, are intercalated as a bi-layer with their cavity axes perpendicular or parallel to the phosphate layers. Assuming hexagonal close packing of CDen molecules in a plane perpendicular to their cavity axes, the effective area per molecule is evaluated as $2\sqrt{3} \times (15.4/2)^2$ or 205 Å². The effective area per POH site in α -ZrP is 24.3 Å² (ref. 7). Hence, the maximum values of x and Δ for the perpendicular arrangement can be calculated, respectively, as 2× 24.3/205 = 0.24 and as twice 11.8 Å, which is the sum of the thickness of the torus and the extended chain length of the aminoethylamino group, or 23.6 Å. These calculations are not consistent with the observed data. On the other hand, the parallel arrangement yields a maximum x value of $2 \times 24.3/(15.8 \times 8.0) =$ 0.40 and a minimum Δ value of 15.4(1+ $\sqrt{3/2}$) = 28.7 Å, in fairly close agreement with the observations. Thus, we propose the model shown in Fig. 2 as the probable arrangement of CDen molecules in the inter-layer space of α -ZrP. This model gives a ξ value for sample A of 0.368/0.40 = 92.0%, which is close to the value roughly estimated from the X-ray observations. It can also be assumed that sample A is a mixture of 92 mol% of a complex, $Zr(HPO_4)_2(CDen)_{0.4} \cdot 5.7H_2O_1$, and 8 mol% of α -ZrP.

Referring to the crystal structure of α -ZrP, the POH groups pointing up or down in each layer are located in a monoclinic cell with dimensions of 9.2 and 5.3 A along the a and b axes, respectively⁶, as shown in Fig. 3. Any two adjacent layers of ZrP are staggered in such a way that the downward-pointing POH groups in the upper layer are shifted by 3.07 Å along the a axis relative to the layer below. It is therefore conceivable that the first intercalated layer of CDen molecules, with their cavity axes parallel to the a axis of the a-ZrP crystal, anchors through the basic termini to every POH site, at 9.2-Å intervals, in every sixth row, 15.9 Å apart, along this axis in the ZrP layer below. The second intercalated layer is probably bonded in the same manner to the ZrP layer above, but is shifted by 7.7 and 8.0 A along the a and b axes, respectively, relative to the first layer. Thus, the parallel bi-layer model suggested above is also consistent with the geometrical arrangement of POH sites at the inorganic layer surface.

Depending on the size and ionic or molecular character of

the substrate, the cyclodextrins and their adducts are crystallized as empty molecules or as inclusion complexes, with channel or cage structures in which the cyclodextrin molecules are stacked like coins in a roll or arranged in a herring-bone pattern⁵. The channel structure is formed only as inclusion complexes with long-chain molecules such as poly-iodine. As the hydrate of β -cyclodextrin contains 7 water molecules within the cavity is probable that $0.4 \times 7/5.3 = 49\%$ of the water molecules in sample A are located in the cavity of the intercalated CDen molecules. According to thermo-gravimetric observations, this sample released 85 mol% of its water during heating to 120 °C, and the dehydrated solid re-adsorbed 92 mol% of the desorbed water by exposure to saturated water vapour at 25 °C, followed by air-drying under the same conditions as for sample A. These preliminary results and the above geometrical considerations suggest that the CDen molecules in one intercalated layer are arranged with their cavity axes parallel to the inter-layer surface, either in alignment to form empty channels, 6 Å in diameter, or, if displaced, with bottlenecks large enough to allow water molecules 2.65 Å in diameter to diffuse. Thus, the dextrin moiety of the CDen-ZrP may possess a zeolitic character, at least for small molecules such as water and hydrogen, although definite conclusions must await further work. Complexes of α -zirconium phosphate with CDen or other cyclodextrin derivatives may prove useful as solid supports in gas or liquid chromatography and as micro-encapsulating agents for various substances such as drugs.

The remarkable distinction between the compositions of ocean island basalts (OIBs) and mid-ocean ridge basalts (MORBs) provides an important constraint on models of mantle composition and structure ¹⁻³. Previous studies of OIBs⁴⁻⁸, however, have emphasized regional isotopic variations, often relying on a small number of samples from many separate volcanoes. Although this type of sampling has now established the basic range of isotopic variations, with the notable exception of the Hawaiian Islands there is little information on either spatial or temporal variations within a single volcano. Here we report isotopic (Sr, Nd and Pb) and K-Ar age measurements for tholeiites, alkali basalts and differentiated rocks from the island of Ua Pou. In this island volcanism spanned the interval from 5.6 to 1.8 Myr, with the ratio of highly to moderately incompatible trace elements increasing

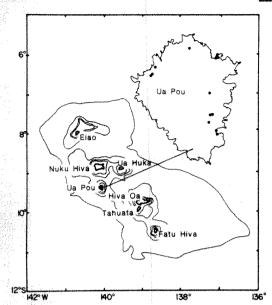

Fig. 1 Map of the Marquesas Islands, an age-progressive volcanic lineament in the south-central Pacific basin, showing the island of Ua Pou. Solid circles (on the enlarged map of the island) mark the location of samples (tholeiites, alkali basalts and differentiates) analysed in the present study.

with time; however, in contrast to Hawaii, ⁸⁷Sr/⁸⁶Sr and ²⁰⁷Pb/²⁰⁴Pb increased while ¹⁴³Nd/¹⁴⁴Nd decreased from the tholeitic to alkalic magmas. The total variation in isotopic composition within this single island is nearly as great as within the entire French Polynesian region^{8,11,12}, and argues against systematic geographical correlations¹³.

The island of Ua Pou, at 9°24′S, 140°04′W, is one of a chain of more than 20 volcanic islands and seamounts which constitute the Marquesas archipelago in the south-central Pacific Basin (Fig. 1). These volcanoes are linearly arrayed in a WNW-ESE direction, sub-parallel with other young intra-plate Pacific island chains. This characteristic geometry and the reported southeasterly progression in volcano ages^{14,15}, from 6.3 to 1.4 Myr, has linked Marquesan volcanism to a hotspot origin. The abyssal (>4,000 m) ocean floor on which these islands were constructed formed at the Galapagos Rise (ancestral East Pacific Rise) between 50 and 60 Myr (ref. 16).

Ua Pou hosts a particularly wide range of rock compositions, from tholeitic to alkalic basalts; the latter have undergone low-pressure fractionation towards trachytic and phonolitic rocks^{17,18}. Although tholeites are the main rock type in the Hawaiian islands¹⁹, they have not been reported elsewhere in the French Polynesian region; their occurrence in the initial stage of volcanism at Ua Pou suggests that tholeitic eruptions may occur throughout this region, but may be almost totally confined to submarine portions of the volcanoes.

We report here age determinations for rocks from Ua Pou. Previous age studies¹⁴ on other islands from the Marquesas chain have documented an age progression in volcanism from north-west to south-east at a rate of ~10.4 cm yr⁻¹ (ref. 9). From this regular age distribution along the lineament, the expected age range at Ua Pou is 4.0-2.7 Myr. Re-examination²⁰ of the published age data showed that at the islands of Nuku Hiva and Hiva Oa dated rocks defined two age groups separated by about the same timespan, 0.6 Myr. Furthermore, at each island the older group was predominantly olivine tholeitte while the younger group was alkali basalt. To investigate this apparent petrogenetic evolution at individual Marquesan volcanoes, additional sampling was undertaken by one of us (H.G.B.).

Ua Pou does not exhibit the central collapsed caldera commonly seen at other Marquesas Islands; instead, the island's

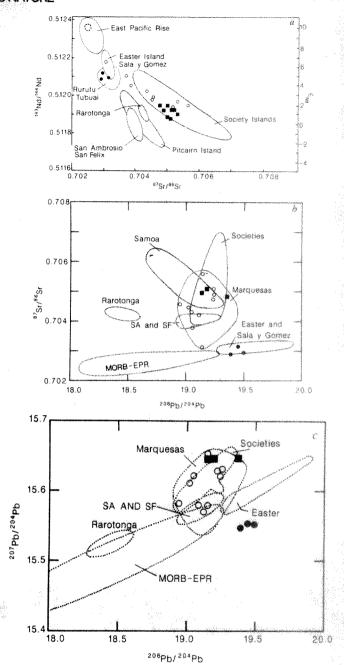

Fig. 2 Isotopic compositions of lavas from Ua Pou compared with those for other basaltic rocks from the south-central Pacific basin. a, 143 Nd/144 Nd versus 87 Sr/86 Sr; b, 87 Sr/86 Sr verus 206 Pb/204 Pb; c, 207 Pb/204 Pb versus 200 Pb/204 Pb. Fields of data are from ref. 25 for islands and East Pacific Rise, except Rurutu and Pitcairn Islands 30. Solid circles and squares are tholeities and alkali basalts, respectively, from Ua Pou. Open circles are other analysed samples from the Marquesas Islands 12. SA, San Ambrosio; SF, San Felix; EPR, East Pacific Rise.

centre is a complex zone of high-level intrusions of trachytic and phonolitic rocks which have obscured the early shield structure of the volcano. Shield lavas outcrop around the perimeter of the island, in stream valleys, in road cuts and along wave-cut cliffs. The samples analysed in this study are well distributed, coming from the northwestern, northern and eastern sides of the island (Fig. 1).

Initial studies¹⁸ of trace element compositions of tholeittes and alkali basalts collected from Ua Pou revealed striking differences in the inferred source compositions for the two groups. Rocks which plot as tholeittes in a standard alkalis versus silica diagram predate the alkali basalt assemblage. The

 87 Sr/ 86 Sr and 143 Nd/ 144 Nd ratios are normalized to 86 Sr/ 88 Sr = 0.1194 and 146 Nd/ 142 Nd = 0.636151, K-Ar ages were calculated using the following decay and abundance constants: $\lambda_e = 0.581 \times 10^{-10} \text{ yr}^{-1}$; $\lambda_B = 4.963 \times 10^{-10} \text{ yr}^{-1}$; 40 K/K = 1.167 × 10⁻⁴ mol mol⁻¹ respectively. For the standard NBS 987, 87 Sr/ 86 Sr = 0.71023 and for BCR-1 143 Nd/ 144 Nd = 0.511833. Rb, Sr, Sm and Nd concentrations are from ref. 18.

tholeiitic phase of volcanism (5.6-4.5 Myr) is separated from the alkali basalt eruptions (2.9-2.7 Myr) and subsequent flows and intrusions of liquids evolved by high-level fractional crystallization (2.5-1.8 Myr). The entire age range of subaerial volcanism at Ua Pou is ~3.8 Myr (Table 1). The apparent 1.6-Myr hiatus between the tholeiitic and alkalic stages of volcanism could be the result of incomplete sampling and may be reduced by future geochronological studies on well-mapped sections. The progression from tholeiitic to alkalic volcanism at Ua Pou and its likelihood at the neighbouring islands of Nuku Hiva and Hiva Oa²⁰ is reminiscent of the volcanic evolution of the Hawaiian Islands¹⁹. In the Marquesas Islands, however, no very undersaturated, post-erosional eruptions have followed the alkali basalt stage. It is probable, therefore, that each of the Marquesas islands evolved through a common sequence. Initially, eruptions may have been a mixture of tholeiitic and alkalic compositions, as seen at Macdonald²¹ seamount at the southeastern end of the Austral Islands, and Loihi seamount²² in the Hawaiian Islands. Tholeiitic compositions dominated the early shield-building phase, which at Ua Pou barely reached sea level. This was followed by eruptions of alkali basalt and, later, highly evolved rocks. It is not yet known whether the change from tholeiites to alkali basalts occurred as a gradual transition or as a sharp compositional break after a significant hiatus in volcanic activity.

Major and trace element concentrations for Ua Pou rocks have been reported elsewhere 17,18. Liotard et al. 18 identified tholeiitic rocks at many of the Marquesas Islands and, in particular, quartz-normative tholeiites at Ua Pou, in addition to the earlier described alkali basalts. The tholeiites and alkali basalts cannot be related to one another by either variable partial melting from a common source or fractional crystallization from a parental melt, because of many clear differences in their trace element patterns. Both groups are enriched in light rare earth elements, relative to MORBs, but whereas the alkali basalts exhibit uniformly steep patterns, the tholeiltic samples show much flatter profiles between La and Sm. The tholeiite trace element patterns are similar in shape to those for Hawaiian tholeiites^{23,24}, with normalized La = normalized Ce, but abundances are higher in Ua Pou tholeiites. Tholeiites and alkali basalts at Ua Pou can also be distinguished by Zr/Nb (11.3 versus 4.8, average values, respectively), La/Nb (0.85 versus 0.98) and La/Ce (0.37 versus 0.51). In addition, on a spidergram diagram the tholeiites show significant depletions of Ba, Rb, Th, K and Sr relative to La.

To characterize further the two magma types present at Ua Pou, we have measured Sr, Nd and Pb isotopic compositions (Table 1). Previous isotopic studies of Marquesas Islands rocks^{11,12,25} have not recognized the importance of the tholeites,

nor have they examined the compositional variation with age at a single island. Our results are in excellent agreement with the isotopic analyses of alkali basalts from Ua Pou reported by Vidal et al.¹². The data were obtained using separation techniques and mass spectrometric analysis, as described in refs 26 (Sr and Nd) and 27 (Pb). Measured Sr, Nd and Pb isotopic ratios are generally within the analytical uncertainty of initial ratios because of the young age of the samples. Corrections to ⁸⁷Sr/⁸⁶Sr were applied only to the high Rb/Sr phonolite samples. Our results are plotted on three diagrams: ¹⁴³Nd/¹⁴⁴Nd against ⁸⁷Sr/⁸⁶Sr (Fig. 2a), ⁸⁷Sr/⁸⁶Sr against ²⁰⁶Pb/²⁰⁴Pb (Fig. 2b), and ²⁰⁷Pb/²⁰⁴Pb against ²⁰⁶Pb/²⁰⁴Pb (Fig. 2c).

Tholeiites are distinguishable from alkali basalts and differentiated rocks using each of the three isotopic systems. The strontium composition of the tholeiites is among the least radiogenic reported from oceanic islands, while the alkali basalt ⁸⁷Sr/⁸⁶Sr values fall in the middle of the range for other Marquesas and Society Islands^{8,11,12}. The corresponding 143 Nd/ 144 Nd values are also distinctive ($\varepsilon_{Nd} = 4.6-5.5$ for tholeiites verus 0.6-2.1 for alkali basalts) and, together with the Sr data, form an array parallel to the Society Islands compositions but oblique to the mantle array⁵⁻⁸. The extreme isotopic heterogeneity of the French Polynesian region has been noted, but at Ua Pou, as recognized for Nuku Hiva by Vidal et al. 12, nearly the entire range of variability exists on the scale of a single island. At Ua Pou the tholeiltic magmas have low 87Sr/86Sr ratios and moderate 143 Nd/144 Nd ratios, indicative of a mantle source with low time-integrated Rb/Sr and a (chondrite-normalized) Nd/Sm < 1. The later alkali basalt magmas have high 87Sr/86Sr and low 143Nd/144Nd, which would derive from a less depleted mantle source. This contrasts with the Hawaiian Islands volcanism, where the tholeiites have higher 87Sr/86Sr and lower $\varepsilon_{\mathrm{Nd}}$ values than the alkali basalts and post-erosional lavas^{9,10}.

The Pb compositions of the two magma types are equally distinct, as seen in the $^{207}\text{Pb}/^{204}\text{Pb}$ versus $^{206}\text{Pb}/^{204}\text{Pb}$ diagram (Fig. 2c). The tholeiites are most similar to rocks from Easter and Sala y Gomez Islands near the East Pacific Rise²⁵, whereas the alkali basalts lie in the field of other reported Pb isotopic analyses from the Society and Marquesas Islands^{12,25}. The Pb isotopic compositions of the Ua Pou tholeiites are not as extreme as those of rocks from Tubuai¹² (Austral Islands) which exhibit similar low $^{87}\text{Sr}/^{86}\text{Sr}$ and moderate ε_{Nd} . They are similar, however, to analysed rocks from Rimatara²⁸ and Rurutu²⁹, neighbouring volcanoes in the Austral Islands.

There has been much recent interest in the geographical distribution of isotopic compositions at oceanic islands, culminating in the Dupal anomaly proposal¹³, which postulates a region of higher ⁸⁷Sr/⁸⁶Sr, ²⁰⁷Pb/²⁰⁴Pb and ²⁰⁸Pb/²⁰⁴Pb, circling the globe at ~30° S. The new isotopic data for Ua Pou presented

here do not, however, support this view. The Marquesas Islands lie within the proposed Dupal anomaly belt, but only the alkali basalts have the appropriate radiogenic compositions. Apparently both Dupal and non-Dupal mantle reservoirs have been tapped at Ua Pou. The same sequence might also be seen at other French Polynesian islands, if the suspected early tholeite phase of volcanism could be sampled. Hence, the regional significance of the Dupal anomaly, at least in this area, is questionable (see also refs 8, 26, 30).

It is evident from trace element and isotopic compositions that the tholeiites and alkali basalts at Ua Pou cannot be related by variable degrees of partial melting or crystal fractionation of primary melts from a common mantle or lithospheric source. Thus at least two, and probably three distinct source endmember compositions have contributed to volcanism at this island. In addition, the alkali basalts postdate the tholeiites in a clear age progression implying that the chemically distinct sources were tapped at different times. This suggests that the sources are not ubiquitous and continuously available for melting, but are likely to be physically separate. We will consider two possibilities for the spatial distribution of these source components: first, partial melting of both the mantle plume and the overlying lithosphere, and second, melting of the plume alone. In the first case the lithospheric mantle and plume have differing isotopic compositions and are the sources for the tholeiitic and alkali basalts respectively; in the second, both the alkalic and tholeiitic melts are derived from the plume, implying an isotopically heterogeneous plume.

The lower oceanic lithosphere probably consists of an unmelted mix of enriched mantle blobs and depleted asthenosphere which could possess considerable isotopic heterogeneity $^{26,31-33}$ (Fig. 3a). Samples from the East Pacific Rise exhibit a rather small range of 87 Sr/ 86 Sr and $\varepsilon_{\rm Nd}$ compositions (Fig. 2a), but are quite variable in 206 Pb/ 204 Pb composition 25,33 (Fig. 2b). Variation in these MORB compositions can be explained by mixing melts from depleted upper mantle with those from a small proportion of enriched mantle of the Rurutu/Tubuai type (low 87 Sr/ 86 Sr, moderate $\varepsilon_{\rm Nd}$, high 206 Pb/ 204 Pb). Interestingly, rocks from Easter and Sala y Gomez Islands have compositions at the high- 206 Pb/ 204 Pb end of this trend 25 (Fig. 2b). Mantle upwelling in this region of the East Pacific Rise may be a major source for the enriched mantle blobs which became incorporated into the lower oceanic lithosphere by thickening of the plate during cooling away from the spreading centre.

At Ua Pou we propose that such heterogeneous oceanic lithosphere of 50-60 Myr age approached and crossed the Marquesas hotspot (Fig. 3a). Melts and heat from the mantle plume entered the lower lithosphere, where wall rock reached temperatures sufficient to melt. The plume and lithosphere melts could then mix to produce the magmas seen at the island. The trace element and isotopic compositions of the mixed magmas would vary depending on the degree of melting of each source and the proportions of melt contributed. At Ua Pou the isotopic composition of the early tholeiitic phase lies on a mixing line between MORB and Rurutu/Tubuai compositions, and reflects the proposed composition of the lower oceanic lithosphere beneath the island. Hence, in this model, melting of the lower lithosphere was significant and dominates the composition of tholeiitic magmas.

As the volcano migrated away from the hotspot, temperatures at the base of the lithosphere decreased. Smaller degrees of melting (of alkali basalt character) developed in the margin of the plume (Fig. 3a). These melts passed through the same column of oceanic lithosphere which had earlier yielded its low-temperature melting fraction; hence, the wall rock was much more refractory and less assimilation occurred at this stage, so that the alkali basalt compositions essentially reflect the isotopic composition of the plume. Contemporaneous with this phase of Ua Pou volcanism was tholeitic, shield-building volcanism at Hiva Oa, the next major volcano upstream, and perhaps the

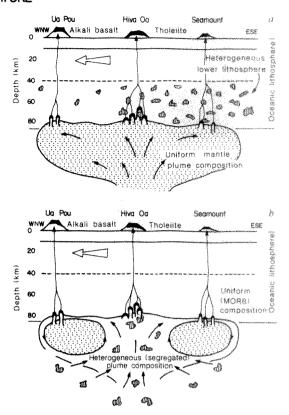

Fig. 3 Two models for the isotopically distinct magmas at Ua Pou. illustrated by vertical cross-sections along the line of the Marquesas Islands. Both models show volcanic activity at ~2.5 Myr, when alkali basalts erupted onto an older tholeiite shield at Ua Pou, concurrently with tholeiitic basalts at Hiva Oa and, possibly, with the initial seamount basalts beneath Fatu Hiva. a. Heterogeneous lower lithosphere. The plume (~400 km diameter) has a uniform, undepleted isotopic composition and is crossed by a Pacific plate composed of an upper section of uniform, MORB-like isotopic composition formed at the East Pacific Rise and an isotopically heterogeneous lower lithosphere accreted to the plate as it cooled away from the spreading ridge. Tholeiitic melts are formed over the centre of the plume as melts from the plume mix with melts from the lower-lithosphere wall rock. Alkali basalt melts erupt from the margin of the plume, where temperatures are cooler, and pass through previously heated lithosphere without significant contamination. b. Heterogeneous plume. The lithosphere has a uniform, MORB-like isotopic composition throughout and passes over a plume which has developed large-scale chemical heterogeneities by entraining depleted upper mantle material during its diapiric rise³⁴. The original plume material concentrates in a torus around the plume margin (shaded), while entrained material flows into the centre³⁵. Hence tholeiitic melts from the plume centre are MORB-like in isotopic character, whereas alkali basalt melts from the margin are more like the original plume. The lower lithosphere may melt but the isotopic differences in erupted magmas are controlled by heterogeneities in the plume.

seamount phase at Fatu Hiva, another 100 km to the south-east. From this model we would expect the same correlation of trace element and isotopic composition with time to emerge at other Marquesas islands.

An analogous model for the origin of Hawaiian tholeiitic and alkali basalts has been proposed by Chen and Frey. At Hawaii, however, there is an inverse correlation between 87 Sr/86 Sr and abundances of incompatible elements; that is, the tholeiitic phase is dominated by the composition of melts from the plume, whereas the alkali basalts are thought to reflect the composition of the lower lithosphere. This relationship is thought to result from small degrees of melting of the lower lithosphere and variable proportions of mixing with plume-derived melts. Although lithosphere melting occurs during the tholeiitic phase,

the volume of melts from the plume is sufficiently high that these determine the composition of Hawaiian tholeites. During the formation of alkali basalt melts, however, very small (<1%) degrees of melting of the wall rock produce high concentrations of trace elements which dominate the composition of smallvolume plume melts. Thus the isotopic composition of the Hawaiian alkali basalts reflects that of the lower lithosphere.

The source end-members for melting and magma mixing are different for the two island chains. At Ua Pou the enriched mantle, or plume composition, has 87 Sr/ 86 Sr > 0.7053 and ε_{Nd} < 0.5 and lies to the right of the Sr-Nd mantle array. This may be similar to, but possibly not so extreme as, the plume component for Society Islands alkali basalt magmas^{1,12}. The lower lithosphere beneath Hawaii, as reflected by the isotopic composition of the alkali basalts, does not appear to contain the Rurutu/Tubuai component seen in the Ua Pou tholeiites. This model therefore requires that the oceanic lithosphere of the Pacific plate has accreted mantle blobs of different isotopic character.

An alternative explanation for the isotopically distinct phases of tholeiitic and alkalic volcanism at Ua Pou is that heterogeneities occur within the plume or diapir itself. These heterogeneities may be either a consequence of initial heterogeneities in the plume source, or result from the incorporation of asthenospheric mantle material into the diapir during its ascent. Recent experimental and theoretical studies 34,35 have demonstrated that thermally activated diapirs will entrain a significant quantity of surrounding mantle material during their ascent. This is illustrated in Fig. 3b, where the central portion of the diapir consists of entrained depleted upper mantle (MORB-like plus mantle blobs), while the original plume material is contained in an outer torus. Tholeitic melts are generated over the centre of the plume while smaller-volume alkali basaltic melts form over the perimeter. If isotopic heterogeneities are distributed uniformly through the diapir, then isotopically distinct magmas could be formed by variable degrees of partial melting. Larger degrees of melting (tholeiite) would tend to homogenize the variable composition of the diapir, whereas smaller degrees of melting (alkali basalt) would emphasize the composition of incompatible-element rich segregations^{31,32}

We thank W. F. McDonough for technical assistance and thoughtful discussions, and W. M. White for data in advance of publication. We also thank Y. and J. Hituputoka and J.-L. and C. Candelot for their assistance during fieldwork on Ua Pou. R.A.D. acknowledges the support of NSF and H.G.B. the support of ORSTOM.

Geophysical evidence for the East Antarctic plate boundary in the Weddell Sea

Yngve Kristoffersen & Kristen Haugland

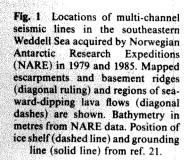

Seismological Observatory, University of Bergen, Allegt. 41, 5000 Bergen, Norway

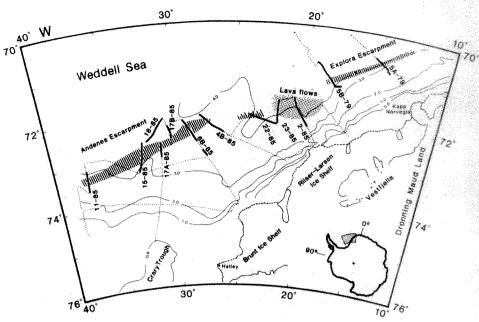

An improved Gondwanaland reconstruction compatible with geological and geophysical information from the surrounding oceans and continents seems to require microplates to solve the enigmatic pre-early-Mesozoic tectonic relation between West and East Antarctica1. New multi-channel seismic reflection data from the southeastern Weddell Sea acquired during the 1984-85 Norwegian Antarctic Research Expedition (NARE) have outlined a linear WSW-ENE-trending basement ridge buried below the continental slope over a distance of 700 km. This structural high truncates the trend of the large sedimentary basins below the Filchner and Ronne ice shelves and may continue to within a few hundred kilometres of the Antarctic Penninsula. We interpret the basement ridge as part of the East Antarctic plate boundary during the break-up of Gondwana. The morphology and structure of this boundary show greater apparent similarity to a rifted or obliquely rifted margin than to the sheared margin which is predicted by current reconstructions^{2,3}. A linear East Antarctic plate margin extending to the vicinity of the Antarctic Peninsula makes any post-rift microplate motion in the Weddell Embayment unlikely.

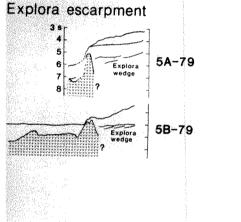

Major linear basement highs have been found below the lower continental slope of the southeastern Weddell Sea margin (Fig. 1). In the north-east, the Explora Escarpment⁴-is characterized by a well-defined 10-20-km-wide basement ridge of 1-2 km elevation with respect to hyperbolated acoustic basement on the seaward side (Fig. 2). On the landward side, a wedge of seawarddipping seismic reflectors, the Explora wedge, unconformably overlain by a 1-2-km-thick section of nearly flat-lying seismic sequences, abuts the ascarpment. Towards the south-west (20 °W), the Explora Escarpment becomes more subdued. The new NARE seismic data demonstrate that a major basement structure collinear with the Explora Escarpment extends at least 700 km farther towards the south-west, but also reveal considerable lateral variation in basement morphology (Figs 1, 2). Between 19 and 23° W a sharp, piece-wise-continuous reflector forms the upper boundary of a sequence of low-frequency seismic reflections whose landward termination is abrupt in some places and more diffuse in others (Fig. 3). We interpret these seismic reflection events as representing a region of seaward-dipping lava flows. We note that the top of this sequence is at a level comparable to the top of the escarpments to the north-east and west.

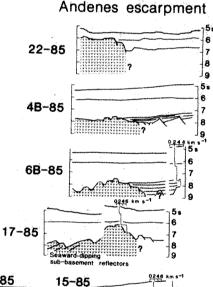

Further west, between 23 and 25° W, is a zone where acoustic basement forms a steep, landward-facing escarpment with downfaulted blocks of lava flows (?) at its base (Fig. 2, line 22-85). Here the escarpment appears to be offset from the landward boundary of the lava pile to the north-east.

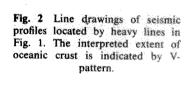

At 26° W, the WSW-trending collinear basement structure is a subdued, 15-30-km-wide ridge with a relief of ~600 m which increases westwards to >2,000 m at 32° W (Fig. 2). We name the basement structure between 23 and 38° W the Andenes

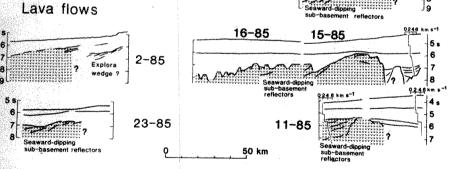

Escarpment after the expedition vessel Andenes of the Norwegian Coast Guard.

The Andenes and Explora Escarpments form a linear basement structure >1,000 km long which coincides with the transition between regions of contrasting reflection characteristics of the transition between terms of contrasting reflection characteristics of the transition between regions of contrasting reflection characteristics of the transition of the t

On the seaward side of the basement ridge is an uneven coustic basement with abundant diffraction hyperbolae, with trong similarity to the acoustic character of oceanic crust (Fig. 1, lines 5B-79, 16-85 and 17-85). There is also evidence of eaward-dipping, low-frequency, sub-basement reflectors leveloped seaward of the escarpments (Fig. 2, lines 11-85, 6-85, 17-85 and 23-85).

On the landward side, the Explora wedge of seaward-dipping and divergent reflectors constitutes the deepest seismic sequence landward of the Explora Escarpment, and acoustic basement is observed only on isolated highs⁴. However, west of 23° W, we can observe acoustic basement for >150 km landward of the Andenes Escarpment and interpret it as a series of tilted blocks, locally with internal reflectors. Another characteristic feature in this area is the distinct low-frequency acoustic character and undisturbed nature of the material $(v_p > 4.5 \text{ km s}^{-1})$ infilling topographic lows in acoustic basement (Fig. 2, lines 4B-85, 6B-85 and 15-85).

The magnetic signature associated with the Explora Escarpment is a positive magnetic anomaly, whereas the relationship along the Andenes Escarpment is more complex (Fig. 4). On

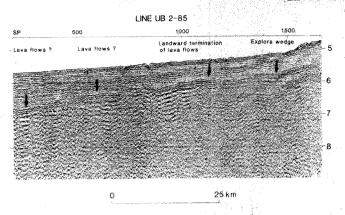

Fig. 3 Seismic reflectors interpreted as seaward-dipping lava flows. SP, shot-point.

the landward side of the escarpments, and paralleling the margin outside the Riiser-Larsen Ice Shelf, is a positive-negative pair of long-wavelength (<100 km) magnetic anomalies which extend southwestward towards the Filchner Ice Shelf and diverge with the trend of the basement ridge^{5,6}. To the south, short-wavelength, high-amplitude magnetic anomalies are associated with magnetic⁵ and acoustic⁷ basement of the east Antarctic craton exposed at the sea floor in a 50-70-km-wide swath along the barrier between Filchner Ice Shelf and Halley (30-37° W). In the northern part of the Soviet survey area (74° S), there is a conspicuous change in magnetic field character towards short-wavelength, high-amplitude, E-W-trending lineations collinear with the Andenes Escarpment. This strongly suggests that the tectonic grain represented by the escarpments may continue

towards the Antarctic Penninsula at least to 55° W.

To the north of the Andenes-Explora escarpments, lineated magnetic anomalies have been related to oceanic crust formed by seafloor spreading^{6,8}. Thus, the escarpments could represent an ancient Gondwana plate boundary in the Weddell Embayment, between oceanic crust to the north and crust of unknown origin to the south.

Gondwana reconstructions using current knowledge of magnetic anomalies in the South Atlantic and Indian Ocean predict large initial strike-slip motion along the Dronning Maud Land (DML) margin during the early opening^{2,3}. The lineated magnetic anomalies observed in the Weddell Sea are strong evidence of underlying oceanic crust formed at a spreading centre subparallel to the Explora escarpment^{6,8}. Thus the Andenes-Explora escarpments may have one or several modes of origin: (1) a fracture zone; (2) a rifted margin; (3) a sheared margin subsequently overprinted by rifting.

The morphological signature of a fracture zone in the oceanic crustal domain is most often a paired basement ridge and trough⁹, whereas a single ridge is most often observed at sheared continental margins^{10,11}. Also, in the latter environment, the ancient fracture zone location at the margin is associated with a precipitous increase in water depth from a shelf or plateau to abyssal depths.

Basement morphology and structure along the Explora Escarpment have affinities with those of a sheared continental margin (Fig. 2). However, the collinear region of lava flows between 18 and 23°W and the Andenes Escarpment shows stronger similarities to a rifted margin segment, the principal evidence being the seaward-dipping sub-basement reflectors to the north of the lava front (line 23-85) or escarpment (lines 16-85, 17-85), respectively. Wedges of seaward-dipping sub-

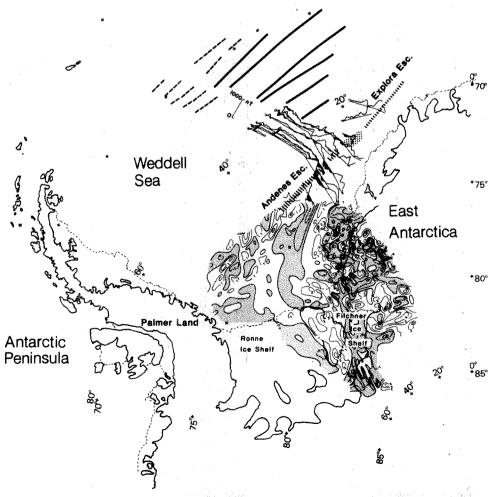

Fig. 4 Compilation of aeromagnetic data⁵ (areas of negative anomalies shaded) and marine magnetic data⁶, together with mapped magnetic lineations in the Weddell Embayment.

basement reflectors, often terminated on the landward side by an escarpment, have been observed along several rifted continental margins and are thought to be at or near the transition from continental to oceanic crust¹². Paralleling the Andenes and Explora escarpments at a distance of <300 km towards the south is the 130-km-long Vestfiella chain of nunataks, which experienced a regime of NW-SE tension during the early to middle Jurassic¹³⁻¹⁵. A 1-2-km-thick section of mostly tholeitic basalts was laid down in subaerial conditions. The volcanic pile is cut by many dykes of predominantly NE-SW strike, and by normal faults with no significant component of strike-slip. Also, basement depths landward of the escarpments (Fig. 2) require a thin crust from isostatic considerations. Thus, the evidence available favours an interpretation of the Andenes-Explora escarpments as structures of a rifted margin or possibly a plate boundary with oblique spreading rather than pure strike-slip. A sequence of events beginning with a large initial shear and subsequent overprint by rifting cannot be ruled out, but is considered less likely in view of the structural history of adjacent land areas, as well as the structural simplicity of the Andenes and Explora escarpments.

A major event in the evolution of the Weddell Embayment was mid-Jurassic crustal extension between the East Antarctic craton and the Pacific facing arc¹⁶, forming major north-south grabens below the Ronne and Filchner ice shelves^{5,17}. A Gondwana plate margin represented by the linear Andenes-Explora escarpments and their western continuation cuts across the early extensional tectonic trend (Fig. 4), indicating a post-mid-Jurassic change in the regional stress field.

A post-rift-phase Filchner microplate^{1,3} probably did not exist. The available multi-channel seismic data^{4,7} (Fig. 1) demonstrate that the sediments below the continental slope and shelf between 15 and 40° W are characterized by a total absence of fold and fault structures induced by post-rift basement tectonics. Also, preliminary results of a seismic survey by Polarstern¹⁸ along portions of a traverse from the East Antarctic craton to the Antarctic Peninsula, outside the Filchner and Ronne ice shelves. show the upper 1 s (two-way travel time) of sediments to be undisturbed except in an area within 150 km of the peninsula. Thus, the locus of any post-rift relative motion between the Antarctic Peninsula 19,20 and the East Antarctic craton is certainly west of 40° W and probably near the peninsula itself.

We thank Captain T. Myhre and the officers and crew of K/V Andenes, also G. Grikurov, I. Kadmina and R. Kurinin at VNIIOkeanologia, Leningrad, Karl Hinz at Bundesanstalt für Geowissenschaften und Rohstoffe, Hannover and colleagues at the Sixth Gondwana Symposium, Columbus, Ohio, for fruitful discussions. Capacity of purified Lyt-2⁺ T cells to mount primary proliferative and cytotoxic responses to Ia tumour cells

J. Sprent & Mary Schaefer

Department of Immunology, IMM4A, Scripps Clinic and Research Foundation, 10666 North Torrey Pines Road, La Jolla, California 92037, USA

Allogeneic gene products of the major histocompatibility complex. the HLA complex in man and the H-2 complex in mice, induce T lymphocytes to exert powerful mixed lymphocyte reactions (MLR) and cell-mediated lympholysis (CML). In mice, the subset of T cells carrying the L3T4 surface antigen but lacking the Lyt-2 antigen responds predominantly to H-2 class II (Ia) differences whereas the L3T4 Lyt-2 subset reacts to class I (K/I) differences^{1,2}. For primary responses the stimulus for MLR and CML appears to be controlled by Ia+ cells of the macrophage/dendritic cell lineages, for both L3T4+ and Lyt-2+ cells3-6. The finding that Ia+ cells are required for responses involving Lyt-2+ cells has been taken to imply that triggering of these cells is controlled by la-restricted L3T4⁺ cells^{7,8}. Lyt-2⁺ cells have thus come to be regarded as crippled cells which are heavily dependent on 'help' from other T cells⁹⁻¹¹. This well-entrenched view is challenged by evidence presented here that purified Lyt-2+ cells can give high primary responses to certain Ia tumour cells in vitro.

Recent studies from this laboratory showed that highly purified Lyt-2+ cells were able to mount high primary MLR and CML responses to class I but not class II H-2 differences in

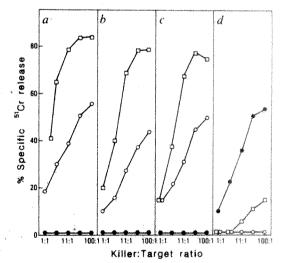

Fig. 1 Cytolytic activity of purified B6 (H-2b) Lyt-2 cells cultured for 4 days in vitro with P815 (H-2^d) tumour cells. Doses of 2×10^6 responder cells were cultured with lightly irradiated (1,500 rad) DBA/2 (H-2^d) spleen cells or with 0.5×10⁶ heavily irradiated (20,000 rad) P815 tumour cells in a volume of 2 ml in 24-well plates; as controls for specificity of lysis, DBA/2 T (J11d-treated LN) cells were cultured with B10 (H-2b) spleen cells. In experiment c, the purified Lyt-2+ cells were pretreated with anti-lab antibody plus C' before culture. After 4 days the cells pooled from several wells were counted and then cultured in varying numbers for 3 h at 37 °C with fixed numbers (10⁴) of ⁵¹Cr-labelled target cells, that is, P815 cells ([]), concanavalin A-stimulated B10.D2 (H-2^d) (()) or B10 (H-2b) () spleen cells; target cells were labelled with $300\,\mu\text{Ci}^{51}\text{Cr}$ per 4×10^6 cells at 37 °C for 1 h and then washed thoroughly. The per cent ^{51}Cr release from target cells was measured by standard techniques, taking release of isotope from detergent-treated cells as 100% release. Each data point represents the mean per cent specific 51Cr release of triplicate cultures; the data in a, b, and in c, d were obtained in two different experiments.

T cells and T-cell subsets were purified from pooled lymph nodes (LN) of adult B6 mice as described elsewhere². To purify T cells, LN cells were pretreated at 37 °C for 1 h in vitro with an anti-B-cell monoclonal antibody (J11d) plus guinea pig serum as a source of complement (C'); the surviving cells (>98% Thy 1⁺) were then passed through Ficoll gradients to remove dead cells. To prepare Lyt-2⁺ cells, LN cells were first pretreated at 37 °C in vitro with a mixture of J11d and anti-L3T4 (GK1.5) antibodies plus C'. The surviving cells were then washed and allowed to adhere to anti-Lyt-2-coated dishes for 1 h at 4 °C. After gently washing non-adherent cells from the dishes, the adherent cells were eluted by vigorous pipetting. The adherent cells were >99% Lyt-2⁺ by FACS analysis and contained no detectable L3T4⁺ cells². For MLR, doses of 2×10⁵ B6 T or Lyt-2⁺ responder cells were cultured in flat-bottom microtitre plates with varying numbers of lightly irradiated (1,500 rad) normal B6 or DBA/2 spleen cells or with heavily irradiated (20,000 rad) in vitro-passaged P815 tumour cells in a final volume of 200 μl. Cells were cultured in RPMI 1640 medium supplemented with 10% fetal calf serum and standard additives²; IL-2 was not added to the cultures. Cultures were pulsed with 1 μCi tritiated thymidine (³H-TdR) 18 h before collection. The data show the mean levels of radioactivity in triplicate cultures. s.d., omitted for simplicity, were generally within 10-20% of the mean. Pretreatment of P815 cells with mitomycin C rather than irradiation led to comparable MLR with B6 Lyt-2⁺ cells.

vitro2; other workers have reported similar findings12. MLR to class I differences were not reduced by removing T cells from the stimulator population or by adding anti-L3T4 monoclonal antibody to the cultures^{2,12}; addition of anti-la monoclonal antibody caused only minimal inhibition of the response. Although these findings suggested that the response of Lyt-2+ cells could not be attributed to minor contamination of the cultures with L3T4⁺ cells, removal of Ia⁺ cells from the stimulator population (spleen cells) virtually abolished the response^{2,12}. At face value the simplest explanation of this finding is that the response of Lyt-2+ cells to alloreactive class I molecules requires co-recognition of class II (Ia) molecules. The problem with this notion is that, unless one invokes cryptic participation of L3T4+ cells, it is difficult to envisage how la molecules might control Lyt-2+ cell induction. In addition, one must account for the fact that certain Ia+ cells-small B lymphocytes—are non-stimulatory for unprimed Lyt-2+ cells⁶. An alternative possibility is that Ia+ cells with stimulatory function display a putative 'second signal' required by Lyt-2+ cells12,13 with the joint expression of Ia molecules and the second signal being largely coincidental. This raises the question of whether some Ia cells might be stimulatory for Lyt-2+ cells. Rammensee et al.14 have shown that Ia Lyt-2+ T cells have the capacity to 'veto' the induction of allogeneic Lyt-2+ cytolytic precursors, the veto function of T cells being attributed to the failure of these cells to express a requisite second signal. Since spleen cell suspensions depleted of Ia+ cells consist largely of T cells, the poor antigen-presenting cell function of Ia spleen cells thus does not preclude the possibility that a spectrum of cell types might act as antigen-presenting cells for Lyt-2+ cells, the notable exception being T cells. To assess this idea, we arbitrarily tested the antigen-presenting function of Ia tumour cells.

Although certain Ia tumours, such as the P815 mastocytoma, are known to elicit primary T-cell responses in vitro^{13,15}, it is unclear whether these responses require help from the L3T4⁺ T-cell subset. Table 1 compares the capacity of B6 (H-2^b) T cells and >99% purified B6 Lyt-2⁺ cells to mount primary MLR to DBA/2 (H-2^d) spleen stimulators (1,500 rad) or P815 (H-2^d) tumour stimulators (20,000 rad) in the absence of added interleukin-2 (IL-2); the P815 tumour, of DBA/2 origin, completely-lacks Ia molecules as assessed by fluorescence-activated cell sorter (FACS) analysis, but is strongly positive for class I

molecules (data not shown). B6 T and B6 Lyt-2+ cells both gave high responses to DBA/2 spleen. Peak responses occurred on day 4 and the responses decreased progressively as the dose of stimulators was lowered. With P815 stimulators, large doses of tumour cells (5×10⁵ per culture) elicited virtually no MLR. Low tumour doses (10⁴-10⁵), by contrast, elicited highly significant MLR. Responsiveness to the P815 tumour seemed to be restricted to Lyt-2+ cells because: (1) responses were appreciably higher with B6 Lyt-2+ cells than with unseparated B6 T cells (Table 1), (2) there was no response to the tumour using purified B6 L3T4+ cells (Table 2, expts a, b) (implying that the tumour cells remained Ia in culture), and (3) in marked contrast to anti-Lyt-2 monoclonal antibody, adding anti-L3T4 to the cultures failed to inhibit the response of B6 Lyt-2+ cells to the tumour (Table 2, expt a; the response to the bm1 and bm12 mutants controlled for the specificity of the blocking effects of anti-Lyt-2 and anti-L3T4 monoclonal antibodies, see Table 2 legend). Heat-killed P815 cells and P815 cells exposed to ultraviolet light were completely non-stimulatory, even when reconstituted with recombinant IL-1 (data not shown).

The response of B6 Lyt-2+ cells to the P815 tumour appeared to be specific for H-2 antigens, as the tumour failed to stimulate H-2-identical DBA/2 Lyt-2⁺ cells (Table 2, expt b) but did stimulate Lyt-2+ cells from another H-2b strain, C3H.SW (Table 2, expt a). Further evidence for antigen specificity was obtained by studying the capacity of the tumour to elicit CML activity In all three experiments performed, two of which are illustrated in Fig. 1, culturing B6 Lyt-2+ cells for 4 days with irradiated P815 cells in the absence of added IL-2 led to high levels of lysis against 51Cr-labelled P815 cells. With concanavalin A. stimulated spleen blast cells as targets, lysis was high on B10.D2 (H-2^d) targets but absent on B10 (H-2^b) targets, implying that lysis was directed to H-2^d determinants rather than to tumour specific antigens. The specific lytic activity of B6 Lyt-2+ cells cultured with P815 stimulators was only slightly lower than with cells cultured with DBA/2 spleen stimulators (compare Fig. 1c and b). Pretreating the B6 Lyt-2+ cells with anti-I-Ab antibody plus complement (C') to remove any residual la cells before culture failed to impair CML activity (Fig. 1c).

The above results indicate that Ia P815 tumour cells are able to stimulate purified allogeneic Lyt-2 cells to proliferate exten sively and differentiate into H-2-specific (presumably class I

Lyt-2⁺ cells were prepared as for Table 1. An analogous procedure was used to prepare L3T4⁺ cells; that is, pretreatment of LN cells with J11d+anti-Lyt-2 (3.168) antibodies+C⁺ followed by positive panning on dishes coated with anti-L3T4. The P815 mastocytoma and the L929-transformed fibroblast line were both totally I-A-negative by FACS analysis but were strongly positive for expression of class I molecules. As for P815, the L929 cells were passaged in vitro without feeder cells; the cells were exposed to 20,000 rad before use as stimulators. The amount of antibody added to the cultures was 2 µl of undiluted ascites fluid for anti-Lyt-2 and 2 µl of 1:10 diluted ascites fluid for anti-L3T4. As controls for the specificity of inhibition by anti-L3T4 and anti-Lyt-2, these antibodies were added to cultures in which MLR were directed solely to a class I H-2 difference (B6 Lyt-2⁺ cells responding to the H-2K-different B6.C-H-2^{bm1} (bm1) mutant) or to a class II H-2 difference (B6 L3T4⁺ cells responding to the I-A-different B6.C-H-2^{bm12} (bm12) mutant); as reported elsewhere² (confirmed in the table), anti-L3T4 selectively inhibits anti-class II MLR whereas anti-Lyt-2 selectively inhibits anti-class I MLR. MLR (mean of triplicate cultures) were measured on day 4 for each experiment shown.

specific) cytotoxic cells in the absence of exogenous IL-2 (although IL-2 production by a subset of Lyt- 2^+ T 'helper' cells' cannot be excluded). Similar findings were observed with the L929 (H- 2^k) Ia transformed fibroblast line (tested only for MLR) (Table 2, expt c). In the case of non-neoplastic cells, we have obtained preliminary evidence that Thy 1 Ia cells from normal bone marrow can stimulate primary MLR by allogeneic Lyt- 2^+ cells (unpublished data). Thus, the capacity to stimulate Lyt- 2^+ cells is apparently not a property unique to Ia tumour cells.

In contrast to these findings with Thy 1⁻ cells, studies with three Thy 1⁺ Lyt-2⁻ T-cell tumours have shown that, like normal T cells, these tumours cannot stimulate unprimed allogeneic Lyt-2⁺ cells in the absence of added IL-2 (unpublished data of

the authors); the reason for this is unclear. Interestingly, the ability of T cells to mediate veto function is largely restricted to activated Lyt-2⁺T-killer cells and is abolished by irradiation¹⁴. Hence, the poor stimulatory function of typical small T cells (for example, anti-Ia+C'-treated spleen) and Lyt-2⁻ T tumours is unlikely to reflect a veto effect. Moreover, we have seen no evidence of suppression when Lyt-2⁺ responders are exposed to a mixture of spleen stimulators supplemented with irradiated small T cells or T tumours. The most likely explanation for the poor stimulatory function of (non-cytotoxic) T cells is that these cells simply lack some requisite second signal required by Lyt-2⁺ cells.

Although the nature of the putative second signal provided by Thy 1 Ia H-2-different tumour cells is unknown, it is

possible that such tumours are directly immunogenic for Lyt-2+ cells in vivo, involvement of L3T4+ cells responding to 'processed' tumour H-2 antigens being unnecessary for tumour rejection. In this respect, we now have preliminary evidence that the subcutaneous growth of P815 tumour cells in irradiated B6 mice can be prevented by mixing the injected tumour cells with unprimed purified B6 Lyt-2+ cells (unpublished data).

Increased levels of myelin basic protein transcripts gene in virus-induced demyelination

In multiple sclerosis, a demyelinating disease of young adults, there is a paucity of myelin repair in the central nervous system (CNS) which is necessary for the restoration of fast saltatory conduction in axons 1,2. Consequently, this relapsing disease often causes marked disability. In similar diseases of small rodents, however, remyelination can be quite extensive, as in the demyelinating disease caused by the A59 strain of mouse hepatitis virus (MHV-A59)3,4, a coronavirus of mice. To investigate when and where oligodendrocytes are first triggered to repair CNS myelin in such disease, we have used a complementary DNA probe specific for one major myelin protein gene, myelin basic protein (MBP), which hybridizes with the four forms of MBP messenger RNA in rodents5. Using Northern blot and in situ hybridization techniques, we previously found that MBP mRNA is first detected at about 5 days after birth, peaks at 18 days and progressively decreases to 25% of the peak levels in the adult5-7. We now report that in spinal cord sections of adult animals with active demyelination and inflammatory cells, in situ hybridization reveals a dramatic increase in probe binding to MBP-specific mRNA at 2-3 weeks after virus inoculation and before remyelination can be detected by morphological methods. This increase of MBP-specific mRNA is found at the edge of the demyelinating area and extends into surrounding areas of normal-appearing white matter. Thus, in situ hybridization with myelin-specific probes appears to be a useful method for detecting the timing, intensity and location of myelin protein gene reactivation preceding remyelination. This method could be used to elucidate whether such a reactivation occurs in multiple sclerosis brain tissue. Our results suggest that in mice, glial cells react to a demyelinating process with widespread MBP mRNA synthesis which may be triggered by a diffusible factor released in the demyelinated areas.

Earlier studies have shown that some MHV-A59 strains can cause chronic demyelination in mice and rats^{4,8-15}. For instance, a high incidence of demyelination occurs in C3H and C57 black mice3,4 after intracerebral inoculation of the prototype MHV-A59 strain16. The virus replicates preferentially in oligodendrocytes, destroying the cells in focal areas of the white matter during the first weeks of infection^{3,4,8-15}. Viral antigen persists in the cytoplasm of oligodendrocytes within the demyelinating

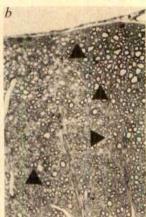

Fig. 1 Micrographs showing demyelinated (a) and remyelinated (b) areas (delineated by arrowheads) in the anterior column of mice at 4(a) and 10(b) weeks post-inoculation with MHV-A59. Active demyelination is seen at 4 weeks while thinly remyelinated axons are seen at 10 weeks. Animals were perfused with 4% glutaraldehyde in Sorensen phosphate buffer, and slices of various levels of the spinal cord were embedded in Epon. 1-µm-thick sections were stained with toluidine blue. ×200.

lesions for up to 4 weeks3. Untranslated viral genome may be present in other areas of the CNS and in other cell types1

In the present investigation, 4-week-old C57Bl/6J mice (obtained from Jackson Laboratories, Bar Harbor, Maine) were injected intracerebrally with 500-1,000 plaque-forming units of MHV-A59 (obtained from Dr L. S. Sturman, New York State Department of Health, Albany, New York). At 1, 2, 3, 4 and 8 weeks after injection, groups of three or four mice were perfused through the heart with periodate-lysine-formaldehyde18, and the brains and spinal cords of the perfused animals were then dissected. Transversely cut slices of various regions of the brain and spinal cord were prepared by freezing and cryosectioning for in situ hybridization as described in Fig. 2 legend. As a probe, we used a small cDNA clone, NZ-112, which encodes amino acids 60-93 of mouse MBP5. By adding 20-25 35S-labelled dATP residues to the 3' ends of the gel-purified DNA fragments using terminal deoxynucleotidyl transferase, a specific activity of 1-2×109 d.p.m. per μg DNA was obtained6,7. Other CNS tissue slices were embedded in paraffin for histological examination and immunocytochemistry. For histology, paraffin sections were stained with Luxol fast blue and cresyl violet or haematoxylin/eosin. For immunocytochemistry, paraffin sections were incubated with dilutions of mouse or goat anti-MBP antibodies and stained by the peroxidase-antiperoxidase method19. In addition, two or three mice at each time point were perfused and processed as described in Fig. 1 legend in order to analyse the details of the demyelinating and remyelinating process in semi-thin plastic sections.

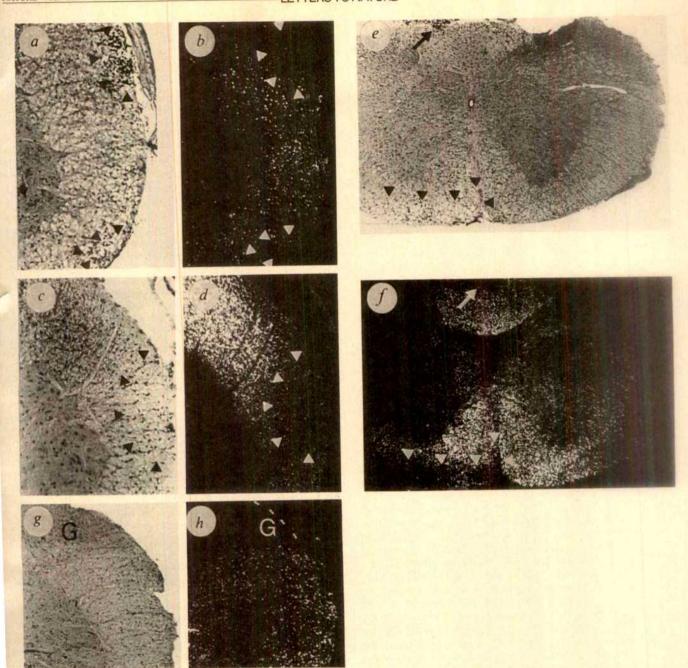

Fig. 2 Micrographs showing the location of MBP-specific transcripts in cervical spinal cords of virus-infected animals at 2(a,b), 3(c,d), 4(e,f) and 8(g,h) weeks post-inoculation. Bright-field views of histological stained sections are shown (a,c,e,g), together with corresponding dark-field cryostat sections after in situ hybridization (b,d,f,h). The number of grains observed in dark field is directly proportional to the amount of hybridization with the MBP probe and thus the number of MBP-specific transcripts. Note some hybridization of the MBP-specific probe in white matter at 2 weeks post-inoculation, with a decrease in labelling in the lesion containing inflammatory cells (delineated by arrowheads). In contrast, at 3 and 4 weeks, intense hybridization is seen in regions surrounding the lesions (delineated by arrowheads) which are devoid of label. Increased hybridization extends into the normal-looking white matter: in f, the left ventral column has a lesion (under arrowheads) but increased label is also seen in the right ventral column. The dorsal right column also has a small lesion (arrow) surrounded by increased label. At 8 weeks (g,h), there is still a slight increase in white matter labelling without the differential distribution (G, grey matter of subtantia gelatinosa) observed in the 3-4-week samples. $\times 200$.

Methods. For these in situ hybridization experiments, samples from the spinal cord were cryoprotected in 15% sucrose (RNase-free) before freezing in liquid nitrogen. Cryostat sections (10 μm thick) were cut and hybridized as described in detail previously⁷. Briefly, the sections were treated with 0.2 M HCl for 20 min, washed in phosphate-buffered saline, incubated with 1 μg ml⁻¹ proteinase K (Boehringer Mannheim) for 15 min at 37 °C, and then with the hybridization mixture without the probe for 2 h. The hybridization mixture was as follows: 50% formamide, 2×SSC, 1×Denhardt's solution, salmon sperm DNA (Sigma) at 450 μg ml⁻¹, Escherichia coli transfer RNA (Sigma) at 500 μg ml⁻¹, 200 μg ml⁻¹ poly(A) (Sigma), 40 nM oligonucleotide d(pT)₈ (Collaborative Research, Inc.). The probe, at a concentration of 100 μg ml⁻¹ and specific activity of 1×10⁷ d.p.m. ml⁻¹, together with the salmon sperm DNA and E. coli tRNA, was denatured for 3 min at 100 °C, quenched on ice for 3 min and mixed with the other constituents of the hybridization mixture with 40 mM dithiothreitol. The mixture was incubated for 15 min at 50 °C, denatured again and incubated at 50 °C for another 15 min. Each section was then incubated at 40 °C with 10 μl of the hybridization mixture in a sealed chamber overnight (about 16 h), washed in 0.1×SSC at 55 °C for 3 h, treated with 75% and 95% ethanol with 300 mM ammonium acetate and air-dried. The slides were dipped in a Kodak NTB-2 emulsion with 300 mM ammonium acetate and stored at 4 °C for 3 days before being developed using standard procedures. The sections were counterstained with cresyl violet before mounting in Permount.

The clinical and pathological features of the disease have been described elsewhere^{3,4}. Briefly, 5-7 days after infection, the mice developed signs of acute disease characterized by apathy, hunched posture, ruffled fur and tremor. Some mice exhibited paresis spontaneously whereas others showed more subtle motor deficits only during testing. During this acute episode, 70% of the mice died, but the remainder recovered from the disease. Signs of motor deficits were less obvious after 4 weeks. Histological examination of the brain and spinal cord at 7 days post-inoculation revealed scattered infiltrations of inflammatory cells. C3H mice, however, showed few perivascular infiltrates3. After 14-21 days, numerous focal lesions exhibited vacuolation and fragmentation of the myelin sheaths. Naked axons, necrotic cells and macrophages containing myelin debris were evident around the lesions. Mild perivascular infiltration with mononuclear inflammatory cells was also seen in these plaques of demyelination. Such demyelinating lesions were present in amost every section of the spinal cords examined and were situated in the central, lateral or posterior columns. Immunocytochemistry revealed a significant decrease in MBP in these lesions, the remaining stain being associated with meylin debris. After 4 weeks, the demyelinated foci were more prominent and most of the degenerated myelin had been phagocytosed (Fig. 1a). A few partially demyelinated axons with abnormally thin myelin sheath were scattered in the lesion at this time. Ten weeks after infection, remyelination was prominant and most axons in the previously demyelinated areas were surrounded by thinner than normal myelin sheaths (Fig. 1b). Immunostaining showed that MBP had reappeared in these areas and was associated with the newly formed myelin sheath. Invasion of the CNS by Schwann cells to remyelinate bare axons20-22 was not detected.

We next examined the cryostat sections of the spinal cord of animals at different stages of the disease after hybridization with the MBP-specific probe and autoradiography (Fig. 2). Since the sections were also stained with cresyl violet, we compared the distribution of the grains (corresponding to the amount of hybridization with the MBP cDNA probe) with the distribution of the lesions. In spinal cord of uninfected mice, more grains were seen in the white matter than in the grey matter, as expected from dot-blot hybridization studies of 1-month-old mice⁵ (Table 1). An unrelated probe (a cDNA of the non-structural phosphoprotein gene of vesicular stomatis virus²³) showed no significant hybridization to grey or white matter in either normal or infected animals. With the MBP-specific probe, however, a slight increase of labelling of the white matter was detected at 2 weeks (Fig. 2b), and fewer grains were seen in areas of white matter inflammation (Fig. 2a, b). At 3-4 weeks post-inoculation (Fig. 2c-f), the intensity of labelling had increased dramatically in some areas of the white matter. When the distribution of the grains in dark field was compared with the size and location of the lesion as seen after cresyl violet staining (Fig. 2a, c, e, g), it became clear that the foci with inflammation and tissue degeneration were devoid of labelling. However, a striking increase in the number of grains was present at the edge of the lesion as well as in the surrounding, normal-appearing white matter of the entire column (Fig. 2d) and even in the opposite column (Fig. 2f). Animals examined 8 weeks after inoculation had slightly higher levels of labelling in the white matter than had the normals (Table 1), but there were no clearly demarcated unlabelled areas such as those seen during the peak of demyelination (Fig. 2g, h).

The evidence presented here suggests that, during a demyelinating process caused by a virus in rodents^{3,4,8-15}, an increase in transcription of the gene coding for MBP, a major myelin protein, occurs early when demyelination is still progressing. Similarly, in CNS demyelinating lesions caused by cuprizone in rats, MBP can be detected by immunocytochemistry in oligodendrocytes before remyelintion²⁴. However, as MBP staining is also seen in macrophages containing myelin debris, it is difficult to distinguish between 'old' MBP and newly synthesized MBP in these lesions. In contrast, in situ hybridization with a MBP-specific probe has revealed an approximate 10-fold increase in the number of MBP transcripts in a widespread area surrounding the demyelinating lesions 3-4 weeks after inoculation (Table 1). In normal rodents only basal levels of MBPspecific RNA are expressed at this stage in development^{5,7}. Thus, in situ hybridization may be the method of choice for detecting the effects of a demyelinating process on myelin protein gene expression. At 2 months post-inoculation, the remyelinated areas showed only a slight increase in MBP mRNA in a diffuse area including the lesion. This suggests that myelin-forming cells have repopulated the demyelinated area and are completing the synthesis of MBP mRNA at that time. It also implies that, in the adult rodent CNS, a cell of the glial lineage may be capable of dividing and probably of migrating into the lesion to repair myelin^{25,27}. Transplantation studies have recently shown that myelinating cells can migrate significant distances in the CNS²⁸. Earlier electron microscope and autoradiographic studies have shown that the cells associated with remyelination after a viral

Table 1 Quantitation of MBP mRNA levels in spinal cord sections of MHV-A59-infected animals using in situ hybridization

Day post-inoculation	0	7	14	20	28	60
No. of mice	4	1	3	4	4	2
Degree of labelling	. +	*	++	++++	++++	++

The appearance of MBP mRNA was quantified by counting grains over the white matter using a scaled reticule and rates as follows: +, 2-3 times more grains over white than grey matter; ++, 3-6 times more grains over white than grey matter; ++++, 10 times more grains over white than grey matter.

disease are newly generated oligodendroglia¹¹. Moreover, recent studies on newborn rat optic nerve have demonstrated the existence of a progenitor cell which, after a number of mitoses, can differentiate into an oligodendrocyte²⁹. In the adult CNS, similar progenitor cells have been identified in the optic nerve and in the rat cerebral cortex²⁵⁻²⁷. Thus, it is now necessary to improve the resolution of our in situ hybridization method and combine this approach with the use of cell-specific markers in order to identify precisely the cell type responsible for remyelination in the CNS.

To our surprise, the increase in MBP gene transcription seemed to radiate from the edge of the plaque, far away into the surrounding normal white matter. This suggests that, in this virus-induced demyelinating disease in mice, a factor may be produced in the lesion which could diffuse into the normal white matter and trigger oligodendrocytes and/or their progenitor cells²⁹ to participate in myelin repair^{11,25-27}. One possibility is that such a factor is secreted by inflammatory cells in the lesion, since it has been shown that spleen cells in mice^{30,31} and T lymphocytes in humans³¹ produce factors which promote proliferation and maturation of astrocytes and oligodendrocytes in vitro. Moreover, interleukin-2 was recently shown to enhance MBP expression in cultured oligodendrocytes.

Tumour necrosis factor α stimulates resorption and inhibits synthesis of proteoglycan in cartilage

Strangeways Research Laboratory, Worts' Causeway, Cambridge CB1 4RN, UK

During inflammatory reactions, activated leukocytes are thought to produce a variety of small proteins (cytokines) that influence the behaviour of other cells (including other leukocytes). Of these substances, which include the interleukins, interferons and tumour necrosis factors (TNFs), interleukin-1 (IL-1) has been considered potentially a most important inflammatory mediator because of its wide range of effects (reviewed in refs 1, 2). In vivo it is pyrogenic and promotes the acute phase response; in vitro it activates lymphocytes3 and stimulates resorption of cartilage4 and bone^{5,6}. Cartilage resorption is a major feature of inflammatory diseases such as rheumatoid arthritis, and IL-1 is the only cytokine hitherto known to promote it. TNFs are characterized by their effects on tumours and cytotoxicity to transformed cells⁷⁻⁹, but share some actions with IL-1. I report here that recombinant human TNF α stimulates resorption and inhibits synthesis of proteoglycan in explants of cartilage. Its action is similar to and additive with IL-1, and it is a second macrophage-derived cytokine whose production in rheumatoid arthritis, or inflammation generally, could contribute to tissue destruction.

Two human TNFs have been isolated: TNF α (refs 8, 9) is a product of activated mononuclear phagocytes, TNF β (ref. 7) of activated lymphocytes. The proteins show about 50% homology in nucleotide sequence and compete for a common class of receptors on the cervical carcinoma line ME-180 (ref. 10). TNF α is probably identical with cachectin¹¹, a factor that suppresses production of lipoprotein lipase in cultured adipocytes, and may play a part in the development of cachexia during infection¹². IL-1 shows some biological similarity to TNF: it is cytotoxic to certain transformed cells¹³ and it suppresses production of lipoprotein lipase in adipocytes¹⁴. Furthermore, cachectin has recently been shown to stimulate production of prostaglandins and latent collagenase by human synovial and dermal fibroblasts in a manner similar to IL-115. In view of these findings, I have investigated the effect of $TNF\alpha$ on both the resorption and synthesis of proteoglycan by explants of cartilage.

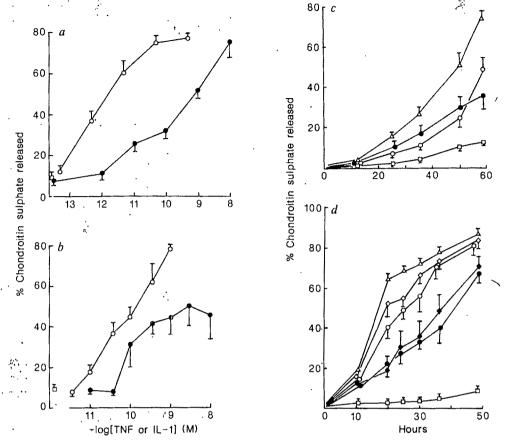

Chondroitin-sulphate-rich proteoglycan is an essential component of the matrix of cartilage since it enables the tissue to resist compression during load-bearing. Loss of proteoglycan, such as occurs in rheumatoid arthritis, osteoarthritis and other joint diseases, results in severe impairment of the function of cartilage. IL-1 is the only purified cytokine known to cause cartilage to degrade its proteoglycan4,16, and to inhibit resynthesis1

Figure 1a shows the amount of proteoglycan (measured as percentage of total chondroitin sulphate) released from porcine articular cartilage during 6 days of culture in the presence of human recombinant TNF α or pure porcine IL-1. The TNF α caused up to 75% of the proteoglycan to be released, although it was less potent than the IL-1, which was significantly active at a 20-fold lower dose (0.5 pM). Figure 1b shows a similar experiment carried out on cartilage from bovine nasal septum which was cultured for a shorter period (48 h): again, the IL-1 was more potent. The time dependence of the release of proteoglycan from bovine cartilage caused by sub-maximal concentrations of the two agents revealed that their effects were additive. Figure 1c shows that 50 pM IL-1 or 290 pM TNFα caused a similar rate of release, and that this was approximately doubled when the agents were combined. Maximal stimulation of cartilage by IL-1 caused more rapid release of proteoglycan than did TNF α (Fig. 1d): results for two concentrations of each cytokine demonstrate that responses were maximal. Supramaximal doses of the two agents in combination caused a rate of release that was considerably faster than that due to $TNF\alpha$ alone, but was not significantly greater than that seen with IL-1 alone. The failure of TNF α to augment the maximal response to IL-1 may be because the limit of the chondrocytes' ability to degrade their matrix in vitro was being approached.

The enzymatic mechanism by which the proteoglycan is degraded in cartilage is not understood. Normally, cartilage proteoglycans aggregate in a specific manner with hyaluronic acid, and it is thought that the large size of these aggregates causes them to be trapped in the matrix. Cartilage stimulated by IL-1 releases fragments of proteoglycan which, as judged by gel filtration, are smaller than normal proteoglycan monomers and are unable to aggregate with hyaluronic acid¹⁸. There is no evidence of degradation of their chondroitin sulphate chains. These changes suggest that degradation is by limited proteolysis of the protein core. The fragments of proteoglycan that were released by cartilage stimulated with TNF behaved similarly on gel filtration to those generated by stimulation with IL-1 (Fig. 2). The bulk of the fragments generated by stimulation with either agent emerged from a Sepharose 2B column at a region between the elution positions of intact proteoglycan and proteoglycan digested with papain (which consists largely of single-chain chondroitin sulphate peptides). Addition of hyaluronic acid to the proteoglycan fragments before chromatography caused little or no formation of aggregates. This suggested that the hyaluronate binding region was blocked or had been lost. When the proteolgycan fragments were chromatographed under dissociative conditions (4 M guanidine-HCl in the chromatographic buffer) the position of the main peak was unchanged. These experiments showed that chondrocytes activated by TNF or IL-1 caused a similar limited proteolysis of the proteoglycans.

In order to study the effect of TNF α on the synthesis of proteoglycan, cartilage was stimulated for 48 h, and 35SO₄ was added to the culture medium for the last 6 h. In this procedure the isotope becomes incorporated into newly synthesized sulphated glycosaminoglycan (mainly chondroitin sulphate). At the end of the experiment the medium and cartilage were digested with papain, and glycosaminoglycan was precipitated from the digests with cetylpyridinium chloride. The amount of radioactivity present in the precipitates was a measure of chondroitin sulphate (and, by inference, proteoglycan) synthesis. In experiments made with porcine articular (Fig. 3a) or bovine nasal septal (Fig. 3b) cartilages, TNF α caused a marked supFig. 1 Stimulation of release of proteoglycan from cartilage TNFα or IL-1. a, Porcine articular cartilage. The amount of chondroitin sulphate released was expressed as a percentage of the total (the content of the medium and tissue combined)21. Results are shown as means of quintuplicate cultures ± s.e.m. , TNF; \bigcirc , IL-1; \square , no addition. b, Bovine nasal septal cartilage. Symbols as for a. c, Time course for bovine cartilage disks cultured as in b with no addition (
), 50 pM IL-1 (O), 290 pM TNF (•), 50 pM IL-1 and 290 pM TNF in combination (A). Chondroitin sulphate released was measured at the indicated times and results are means ± s.e.m. of eight individual disk cultures. d, Time course for bovine cartilage discs cultured as in c, with no addition (□), 30 nM TNF (●), 90 nM TNF (♠), 1.5 nM IL-1 (O), 4.5 nM IL-1 (♦) and 90 nM TNF and 4.5 nM IL-1 in combination (\triangle).

Methods. a, Pieces of articular cartilage were removed from the metacarpal heads of freshly slaughtered young pigs. Pieces (~4 mg wet weight) were maintained for 48 h at 37 °C in CO₂/air 1:19 in culture medium [Dulbecco's modified. Eagle's medium (DMEM)] containing 5% normal bovine serum that had been heat-inactivated at 56 °C

for 30 min). Each was then transferred to a well of a 96-well multititre plate and incubated under the same conditions in 0.2 ml of culture medium, either with no addition, or with human TNF α or porcine IL-1 of pI 5. The medium was changed at 3 days and the culture was terminated after 6 days. Human TNF α was a recombinant protein expressed in Escherichia coli and purified as described previously^{7,22}. Porcine IL-1 was a natural leukocyte protein purified to homogeneity as described elsewhere¹⁶. The pI 5 form rather than the pI 8 form was used for these experiments. After culture the medium and cartilage were separated. The cartilage was digested completely with papain (see legend to Fig. 3). The chondroitin sulphate content of this digest and culture medium was estimated by use of the metachromatic dye, dimethylmethylene blue (Serva); whale chondroitin sulphate (Sigma) was used as a standard. b, Disks (2×1 mm) of cartilage were cut from the bovine nasal septa of freshly killed animals. Disks were precultured for 48 h and then stimulated for 48 h with TNF α or IL-1. The chondroitin sulphate content of medium samples and tissue digests was measured exactly as described for pig particular cartilage.

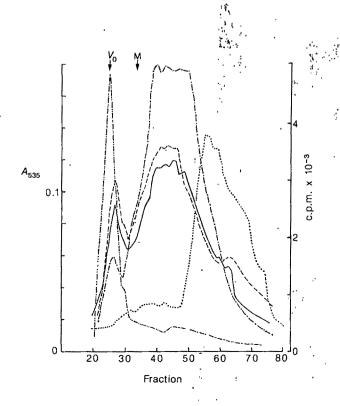

Fig. 2 Gel chromatography of proteoglycans released from stimulated cartilage. Samples of culture supernatants from stimulated bovine nasal cartilage were chromatographed on a column (930× 6.5 mm) of Sepharose 2B (Pharmacia) eluted with 0.5 M acetate buffer pH 5.8. Fractions (0.4 ml) were collected. Proteoglycan was detected as chondroitin sulphate by the dye dimethylmethylene blue (see Fig. 1) and is shown as A_{535} . — , Culture supernatant from bovine nasal cartilage cultured as in Fig. 1 in the presence of 5 nM TNF; ----, the same supernatant to which hyaluronic acid (2%) had been added before chromatography; ----, culture supernatant from cartilage stimulated with 0.5 nM porcine IL-1, and to which hyaluronic acid had been added before chromatography;, a papain digest of proteoglycan extracted from fresh cartilage by 4M guanidine-HCl. -.., proteoglycan (+2% hyaluronic acid) extracted by guanidine-HCl (4M) from unstimulated cartilage that had been biosynthetically labelled with 35SO4 for 24 h, measured as c.p.m. Arrows are: V_0 , void volume; M, elution position of 35SO4-labelled proteoglycan without addition of hyaluronic acid.

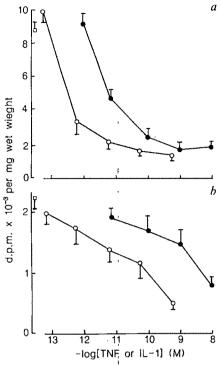

Fig. 3 Effects of TNFα or IL-1 on the incorporation of ³⁵SO₄ into glycosaminoglycans of cartilage. a, Porcine articular cartilage; b, Bovine nasal septal cartilage. Each assay point is the mean of five separate explants \pm s.e.m. \bullet , TNF α ; O, IL-1; \square , no addition. Methods. a, Pieces of pig articular cartilage were dissected, precultured and then stimulated either with TNF α or porcine IL-1 for 48 h exactly as described for Fig. 1, except that the culture medium (DMEM) contained 1% normal bovine serum (heat inactivated) during the stimulation period. For the last 6 h the medium was replaced with SO_4 -free culture medium (still containing $TNF\alpha$ or IL-1) to which was added 2.5 μ Ci ml⁻¹ of ³⁵SO₄ (25-40 Ci mg⁻¹; Amersham). After culture, the cartilage pieces were separated from the medium, briefly blotted to remove excess medium, and then weighted. Each piece was digested at 65 °C for 2 h.in 0.2 ml of 0.05 M sodium phosphate buffer pH 6.5 containing 1 mM EDTA, 2 mM N-acetylcysteine, 28 μg ml⁻¹ papain (Sigma Type III). Samples of medium (0.2 ml) were also digested with 0.1 ml of the papain solution under the same conditions. Chondroitin sulphate (0.1 ml of 2 mg ml⁻¹) was added to all the samples followed by 0.1 ml of cetylpyridinium chloride (10% w/v). Samples were centrifuged, the precipitates were washed twice in 3% cetylpyridinium chloride, then dissolved in 0.5 ml of formic acid and added to 5 ml of a scintillation mixture (Pico-fluor-30, Packard) and counted in a liquid scintillation counter. The radioactivity of the digests of tissue and medium were added together and the results expressed as d.p.m. per mg wet weight of cartilage. b, As for a except that disks of bovine nasal septal cartilage were used (see Fig. 1), and the culture medium contained 5% normal bovine serum throughout the experiment.

pression of proteoglycan production as judged the incorporation of ³⁵SO₄ into glycosaminoglycan, but was less potent than IL-1. The porcine IL-1 inhibited incorporation in porcine articular cartilage in the range 0.1-10 pM; TNF α was 20-fold less active. A similar differential was observed on the bovine cartilage. The lower potency of the human TNF α compared with porcine IL-1 may be due to species differences.

Taken together, the experiments demonstrate that TNF α has a similar action to IL-1 on chondrocytes. It causes them to degrade proteoglycan by limited proteolysis and inhibits their synthesis of new proteoglycan. Exposure of cartilage to either of these leukocyte products during inflammation could lead to loss of proteoglycan and impairment of function; furthermore, their effects may be additive.

Pigs¹⁶, like humans¹⁹, have two different IL-1 proteins: for these experiments the pI 5 IL-1 was used rather than the pI 8

form. The IL-1s are equipotent on cartilage16 and compete for the same receptors on porcine synovial fibroblasts: $TNF\alpha$ at 400 times excess over IL-1) did not compete for these receptors (T. A. Bird and J. S., in preparation). The augmentation of the effect of maximal doses of TNF α by IL-1 reported here is consistent with there being different receptors on chondrocytes for the two cytokines. Since they are apparently not homologous^{8,16}, IL-1 and $TNF\alpha$ would be expected to combine with different receptors. These considerations suggest that chondrocytes (and probably other connective tissue cells) could have two distinct types of receptor (one for IL-1 and one for TNF) whose interaction with ligand promotes resorption of matrix polymers while inhibiting their synthesis. Such a possibility could have important implications for the pharmacological control of inflammatory tissue destruction.

Following submission of this manuscript, Bertolini et al.20 have reported that human TNFs, like IL-1, stimulated Ca2+ release from fetal rat bones.

I thank Dr M. Palladino (Genentech) for supplying TNF, Dr C. A. Dinarello (Tufts University) for suggesting the experiments, Dr J. Tyler (Strangeways Laboratory) for doing the gel chromatography, Mrs V. Curry and Mrs J. Mason for technical help, and the Arthritis and Rheumatism Council for financial support.

Post-translational insertion of a fragment of the glucose transporter into microsomes requires phosphoanhydride bond cleavage

Most eukaryotic secretory and membrane proteins insert co-translationally into the membrane of the rough endoplasmic reticulum (RER), and are targeted there by one or more NH2-terminal or internal signal sequences (for reviews see refs 1, 2). However, little is known about the actual translocation and membrane integration processes. In particular, any energy requirements for targeting and integration have remained obscure because of the inability to uncouple the processes from concomitant protein synthesis. We recently showed that the human glucose transporter (GT), an integral membrane glycoprotein³, can insert post-translationally into dog pancreatic microsomes with low but demonstrable efficiency in vitro, and that a fragment corresponding to the NH2-terminal 340 amino acids and 8 of the 12 membrane-spanning α -helixes of GT (GT-N) can insert with significantly greater efficiency⁴. We report here that post-translational insertion of GT-N into pancreatic microsomes requires energy in the form of a phosphodiester bond, and suggest that co-translational insertion of proteins into the RER may also require energy independent of that used for polypeptide synthesis.

From experiments using in vitro translation and membrane translocation⁵⁻⁸, Walter and Blobel^{1,8} proposed the following sequence of events for the targeting of proteins for translocation across the RER membrane. Initiation of synthesis of a secretory polypeptide starts on a messenger RNA-ribosome complex free in the cytosol. The emergence of an N-terminal signal sequence from the large ribosomal subunit triggers the binding of cytosolic signal recognition particle (SRP) and arrest of polypeptide chain elongation. The complex then binds to the surface of the RER via a transient interaction between SRP and the membranebound SRP receptor⁹⁻¹¹ (docking protein¹²). Integral membrane proteins¹³⁻¹⁷ which may possess one or more^{4,13} N-terminal or internal signal sequences also utilize this targeting process, although specific arrest of polypeptide chain elongation by SRP does not always occur during translation in vitro4,14. Subsequent events in the translocation/integration process remain obscure. particularly whether the nascent chain traverses the membrane through an aqueous pore^{5,18} or directly through the fatty acyl core of the lipid bilayer19.

To investigate the energetics of membrane protein insertion, we used a recently developed in vitro assay in which efficient insertion into RER membranes of a fragment of the human glucose transporter, corresponding to the NH₂-terminal 340 amino acids (GT-N), is uncoupled from protein synthesis⁴.

RNA was transcribed from a SP65 plasmid construction encoding GT-N and used as a template for the synthesis of GT-N in a reticulocyte cell-free translation system. GT-N can insert post-translationally into dog pancreatic microsomes with a conformation resembling that of the corresponding region of the native membrane-bound protein⁴. Figure 1a shows that 50% of GT-N inserted into microsomes is added post-translationally, as monitored by the appearance of the 36,000 (36K) relative molecular mass (M_r) glycosylated form of the polypeptide (GT-N₁) (Fig. 1a, lane 2). Additionally, trypsin digestion of pancreatic microsomes generates the appropriate fragment containing the first six membrane-embedded helices of GT^{3,4} (Fig. 1b, lane 8). The addition of glucose (Fig. 1a, lane 3), hexokinase (lane 4) or glucose 6-phosphate (lane 6) alone had a negligible effect on post-translational insertion; in contrast, depletion of ATP by the addition of both glucose and hexokinase effectively abolished insertion (Fig. 1a, lane 5, Fig. 1b, lanes 3, 6). Because yeast hexokinase can use other purine nucleoside triphosphates as cofactors, although with less efficiency than when using ATP²⁰, we cannot conclude that the observed effect is due solely or directly to the depletion of ATP.

Figure 1b shows that post-translational insertion of GT-N in ATP-depleted extracts could be reconstituted by the addition of excess creatine phosphate. This is demonstrated by the appearance in pelleted microsomes of glycosylated GT-N after the microsomes have been washed in a neutral buffer (Fig. 1b, compare lane 4 with lanes 2 and 3). When the microsomes are washed in buffer at alkaline pH, peripherally associated membrane proteins as well as the vesicle contents are extracted, so that only integral membrane proteins sediment with the microsomes $^{21-23}$. By this criterion, insertion of GT-N into the lipid bilayer was restored after addition of excess creatine phosphate (Fig. 1b, compare lane 7 with lanes 5 and 6). This is also demonstrated by the generation of the glycosylated 22K NH₂-terminal fragment of GT^4 after the addition of excess creatine

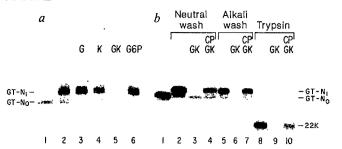

Fig. 1 Membrane insertion of GT-N is inhibited by depletion of nucleoside triphosphates. Synthesis of GT-N mRNA using SP6 RNA polymerase and synthesis of 35S-methionine-labelled GT-N in a reticulocyte cell-free system have been described previously4. Translation was allowed to proceed at 30 °C for 90 min (45 min after net protein synthesis was complete). a, After translation 1 mM cycloheximide was added, sufficient to inhibit incorporation of ⁵S-methionine into GT-N protein by >99% (data not shown). The translation mixture was divided into five 25-µl aliquots and then incubated at 30 °C for 10 min without any additions (lane 2). with 5 mM glucose (lane 3), 1.4 U of yeast hexokinase (lane 4), 5 mM glucose and 1.4 U of hexokinase (lane 5), or with 5 mM glucose 6-phosphate (lane 6). Dog pancreatic rough microsomes (3 equiv.²⁹) were then added and incubation was continued for) were then added and incubation was continued for 20 min. The microsomes were sedimented by centrifugation for 20 min in an Eppendorf microfuge, resuspended in 50 µl of 0.25 M STBS (0.25 M sucrose, 10 mM Tris-Cl pH 7.5, 150 mM NaCl), and re-sedimented. The membrane pellets were dissolved directly in sample buffer and analysed on a 12% polyacrylamide gel using the systems of Laemmli³⁰. Aliquots $(5 \, \mu l)$ of translation reaction to which microsomes were not added were analysed in lane 1; this is the 100% value used here and in subsequent figures to calculate per cent insertion. The gel was washed for 30 min in 10% trichloroacetic acid, 30% isopropanol, treated with Enlightening autoradiography enhancer (Dupont-NEN), dried and exposed to Kodak XAR-5 film for 1 h. b, After translation the reaction was adjusted to 1 mM cycloheximide and 50 µg ml⁻¹ of RNase A and then divided into 20-µl aliquots. Samples were incubated as described above with no additions (lanes 1, 2, 5, 8) or after addition of 5 mM glucose and 1.4 U of hexokinase (lanes 3, 4, 6, 7, 9, 10). Creatine phosphate (20 mM) was then added to some samples (lanes 4, 7, 10) followed by the addition of microsomes (3 equiv.²⁹ per 20-µl reaction; lanes 2-10). After 20 min incubation, the microsomes were sedimented as described above and washed in 0.25 M STBS (lanes 2-4 and 8-10) or 0.25 M STBS adjusted to pH 11.5 with NaOH (lanes 5-7), then analysed as described above. Aliquots (5 µl) of translation reaction to which microsomes were not added were analysed in lane 1. Abbreviations used are: G, 5 mM glucose; K, 1.4 U hexokinase; GK, glucose and hexokinase; CP, 20 mM creatine phosphate; G6P, 5 mM glucose 6-phosphate; GT-N₀, unglycosylated GT-N; GT-N₁, glycosylated GT-N.

phosphate followed by trypsin digestion of the microsomes (Fig. 1b, compare lane 10 with lanes 8 and 9).

After depletion of ATP under the conditions used in these experiments, variable amounts of unglycosylated GT-N sedimented with washed microsomes (Fig. 1a, lane 5; Fig. 1b, lane 3). Only a small fraction of this is due to nonspecific pelleting of GT-N in the absence of microsomes (data not shown). Thus, we do not know whether targeting of GT-N to microsomes is energy dependent.

Figure 2 shows that, after translation, removal of low- M_r components from the lysate by gel filtration inhibits post-translational insertion, as monitored by the appearance of glycosylated GT-N associated with the microsomes (Fig. 2, compare lanes 2 and 3). Addition of 1 mM Mg-ATP (Fig. 2, lane 4) or 10 mM Mg-ATP (Fig. 2, lane 5) to the lysate after gel filtration restored the appearance of glycosylated GT-N. The non-hydrolysable β , γ -methylene ATP analogue did not promote insertion of GT-N, and inhibited the residual insertion observed after gel filtration of the lysate (Fig. 2, compare lane 6 with lanes 2 and 3).

In this assay, ATP and GTP are equally effective in promoting insertion; UTP and CTP are less effective (data not shown).

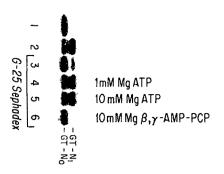

Fig. 2 ATP restores membrane insertion of GT-N in gel-filtered lysates. After synthesis of GT-N in a reticulocyte lysate, as described in Fig. 1 legend, the lysate (100 µl) was adjusted to 1 mM cyclohexamide and centrifuged through two successive 0.9 ml Sephadex G-25 columns equilibrated in column buffer (50 mM HEPES pH 7.5, 5% glycerol, 0.1 M KAc, 5 mM MgAc, 2 mM dithiothreitol, 1% bovine serum albumin, 1 mM TPCK and TLCK, 1 mM cycloheximide). The gel-filtered lysate was then treated with 50 μg ml⁻¹ RNase A for 10 min at 30 °C. Microsomes were then added (3 equiv.29) to 25-µl aliquots without any additions (lane 3) or with 1 mM MgAc-ATP (lane 4), 10 mM MgAc-ATP (lane 5) or 10 mM MgAc-AMP-PCP (lane 6) and incubated for an additional 30 min. The microsomes were sedimented by centrifugation in an Eppendorf microcentrifuge for 20 min, resuspended and washed in 0.25 mM sucrose, 50 mM Tris-Cl pH 7.5, 25 mM KAc, 5 mM MgAc, and analysed by polyacrylamide gel electrophoresis as described in Fig. 1 legend. Aliquots (5 µl) of lysate to which microsomes were not added were analysed in lane 1. A microsomal fraction added to 25 µl of unfiltered lysate was analysed in lane 2.

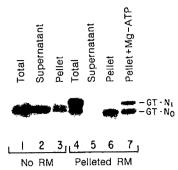

Fig. 3 Only GT-N associated with ribosomes acts as a substrate for membrane insertion. GT-N was synthesized in a reticulocyte lysate as described in Fig. 1 legend. The lysate was then adjusted to 1 mM cycloheximide and fractionated into a ribosomal pellet and a post-ribosomal supernatant by centrifugation for 30 min at 300,000 g in a Beckman TL-100.2 rotor. The ribosomal pellet was resuspended in a volume of column buffer (see Fig. 2 legend) equal to that of the original lysate. Rough microsomes (RM, 3 equiv.²⁹) were then added to aliquots of the unfractionated lysate, postribosomal supernatant and resuspended ribosomes. The sedimented microsomal fractions were then washed and analysed by polyacrylamide gel electrophoresis as described in Fig. 2 legend. Lane 1, 5 µl of unfractionated lysate; lane 2, 5 µl of post-ribosomal supernatant; lane 3, 5 µl of resuspended ribosomes; lane 4, microsomes from 25 µl of unfractionated lysate; lane 5, microsomes from 25 µl of post-ribosomal supernanant; lane 6, microsomes from 25 µl of resuspended ribosome fraction; lane 7, microsomes from 25 µl of resuspended ribosome fraction supplemented with 5 mM MgAc-ATP.

Because enzymes that catalyse the transfer of phosphate from one nucleotide to another (for example, nucleoside diphosphate kinase) may well be present in these crude extracts, and the removal of low- M_r components may not be quantitative, we do not know which nucleotide (or other high-energy phosphate compound) is the proximal source of energy.

Under the washing conditions used in this experiment (25 mM potassium acetate, 5 mM magnesium acetate), a considerable fraction of unglycosylated GT-N sedimented with the microsomes. Only a small fraction of the non-glycosylated GT-N was inserted, since most could be removed by alkali extraction (data not shown). Whether the alkali-labile fraction represents a genuine intermediate in membrane insertion, or simply an adventitious association of the unintegrated protein with the microsomes, is not known.

The GT-N mRNA used in these experiments lacks a termination codon, so that proper polypeptide chain termination and release of the completed polypeptide should not occur. Surprisingly, Fig. 3 shows that about 75% of GT-N synthesized was recovered in a post-ribosomal supernatant (compare lanes 2 and 3) and presumably represents completed and released polypeptides. The remaining 25% of GT-N sedimented with ribosomes and presumably is a completed peptidyl-transfer RNA-ribosome complex. Supporting this latter point is the observation that the yield of GT-N in the ribosomal fraction was reduced by at least 50% if the lysate was incubated with puromycin before sedimenting the ribosomes (data not shown). In this experiment about 25% of GT-N in the unfractionated lysate inserted post-translationally into the microsomes (Fig. 3, lane 4). The GT-N in the post-ribosomal supernatant did not insert (Fig. 3, lane 5). As monitored by the appearance of glycosylated GT-N, very little GT-N in the resuspended ribosomal pellet inserted in the absence of added ATP (Fig. 3, lane 6). Insertion was increased by including ATP in the buffer (Fig. 3, lane 7). Adding a ribosome fraction obtained from reticulocyte lysate not programmed with mRNA to the GT-N in the post-ribosomal supernatant did not reconstitute insertion, indicating that the lack of insertion of released GT-N was not due to the lack of

a soluble factor that sedimented with the ribosomes (data not shown). Thus, the behaviour of GT-N is unlike that of the intact GT, which can insert (with a lower efficiency) into microsomes as a completed polypeptide⁴.

One possible explanation for these observations is that glycosylation of GT-N does not occur in the absence of ATP, and that glycosylation is necessary for insertion. Several considerations argue against this interpretation. Insertion of other proteins into membranes both in vivo and in vitro does not require Asn-glycosylation (see, for example, ref. 24). In our system, glycosylation is unaffected by concentrations of tunicamycin in vast excess of that required to inhibit formation of GlcNAc-P-Pdolichol in vivo and in vitro (our unpublished observations), indicating that de novo synthesis of the dolichol-core oligosaccharide is not required. Furthermore, significant glycosylation of GT-N is observed in the absence of nucleoside sugars (which should not be present at significant levels after gel filtration of lysate or in the resuspended ribosomal fraction: see Figs 2, 3), indicating that elongation of GlcNAc-P-P-dolichol is not required in our system. Thus, sufficient preformed core oligosaccharide-dolichol donor must be be present in our microsomal preparation, and transfer of the core oligosaccharide from the dolichol donor to asparagine residues does not require a nucleotide cofactor²⁵.

Our observations suggest that targeting and/or insertion of GT-N into pancreatic microsomes is dependent on energy in the form of a nucleotide triphosphate cofactor. Whether this dependence involves known factors in the targeting process, or an as yet unknown factor or factors involved in translocation, remains to be determined. Since no ionophore tested (monensin, gramicidin, A23187) blocks insertion (not shown), we feel that hydrolysis of a phosphoanyhdride bond is not used to generate an electrochemical potential across the ER membrane which is in turn used to power translocation. In this respect, post-translational insertion into RER membranes is different from energy-dependent translocation across the bacterial²⁶ or mitochondrial²⁷ inner membrane and sim ilar to polypeptide import into chloroplasts²⁸. We speculate that co-translational insertion of

membrane and secretory proteins into or across the RER also requires energy in addition to that consumed in protein synthesis. This could involve an ATP- or GTP-driven translocase that is part of a transmembrane channel^{5,11} through which the nascent polypeptide moves.

Role of ion flux in the control of c-fos expression

James I. Morgan* & Tom Curran†

Departments of * Neurosciences and † Molecular Oncology, Roche Institute of Molecular Biology, Roche Research Center, Nutley, New Jersey 07110, USA

There has been much interest in the biochemical and biophysical processes that couple extracellular signals to alterations in gene expression. While many early events associated with the treatment of cells with growth factors have been described (for example, ion flux and protein phosphorylation^{1,2}), it has proved difficult to establish biochemical links to gene expression. Recently, the study of such genomic control signals has been facilitated by the demonstration that the c-fos proto-oncogene is rapidly and transiently induced by treatment of several cell types with polypeptide growth factors and other growth modulating substances³ one particular system it has been shown that nerve growth factor (NGF) causes a transient induction of c-fos in the phaeo-chromocytoma cell line PC12, within 15 min⁹⁻¹¹. Furthermore, the magnitude of this induction can be modulated with pharmacological agents such as peripheral-type benzodiazepines (BZDs)9. Thus, the study of c-fos expression in PC12 cells could yield valuable clues to the coupling mechanisms linking cell surface activation to genomic events. Here we demonstrate that c-fos is induced in PC12 cells either by receptor-ligand interaction or by agents or conditions that effect voltage-dependent calcium channels.

In the following experiments the synthesis of the c-fos protein has been monitored by immunoprecipitation after metabolic labelling with 35S-methionine. For quantitative analysis, immunoprecipitates from equivalent amounts of cell lysate, as

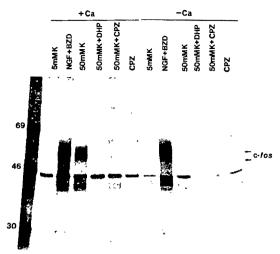

Fig. 1 Induction of c-fos protein by 50 mM potassium is calciumand calmodulin-dependent. PC12 cells were incubated in basal medium with the following additions: 5 mM potassium chloride (5 mM K), 200 ng ml⁻¹ NGF plus 100 μM benzodiazepine (7-3351) (NGF+BZD), 50 mM potassium chloride (50 mM K), 50 mM potassium chloride plus 15 µM dihydropyridine (nisoldipine, 1,4dihydro-2,6-dimethyl-4-(2-nitrophenyl)-3,5-pyridenedicarboxylate) (50 mM K+DHP), 50 mM potassium chloride plus 30 μ M chlorpromazine (50 mM K+CPZ) or 30 µM chlorpromazine (CPZ), in the presence (+Ca) or absence (-Ca) of 1.1 mM calcium chloride. The drugs chlorpromazine and nisoldipine were added to cultures 5 min before the other reagents. In the experiment shown, nisoldipine was used at a saturating concentration (15 μM), however, 50 nM nisoldipine also attenuated potassium-induced c-fos expression (data not shown). Incubation was continued for 30 min at 37 °C then 300 μCi ml⁻¹ ³⁵S-methionine (≈800 μCi mmol⁻¹; Amersham) was added for a further 15 min. Extracts were prepared and immunoprecipitated with fos-specific antibodies. The immunoprecipitation products from 107 c.p.m. of TCA-insoluble proteins were analysed by SDS-polyacrylamide gel electrophoresis (SDS-PAGE). Arrows indicate the position of the c-fos protein. The numbers on the left indicate the relative molecular masses $(M_r s)$ of the ¹⁴C-methylated marker proteins (Amersham). Methods. PC12 cells³³ were cultured in RPMI medium (Gibco) containing 10% horse serum, 5% calf serum and 4 mM Lglutamine. For experimentation, cells were seeded onto 35-mm Petri dishes (Falcon) and allowed to attach and proliferate for 48 h. Immediately before experimentation this medium was removed and replaced with 1 ml of incubation buffer (basal

medium) or 1 ml of Dulbecco-Vogt modified Eagle's medium (DMEM) lacking methionine. Basal medium comprised 20 mM HEPES, 146 mM NaCl, 4.2 mM KCl, 0.5 mM MgCl₂ and 0.2% D-glucose. Preparation of cell lysates, immunoprecipitation, SDS-PAGE and fluorography were as described previously^{6,34,35}. The fos-specific antibodies used were affinity-purified against a peptide predicted from the c-fos nucleotide sequence³⁴

measured by trichloroacetic acid (TCA)-insoluble radioactivity, were compared. Care was taken to ensure that the various treatments did not result in more than a 50% reduction of 35S-methionine incorporation as some inhibitors of protein synthesis can cause an accumulation of c-fos messenger RNA^{3,4,6}. Dose-response analyses were performed for all the agents used so as to obtain the maximal specific effect of each.

We demonstrated previously that NGF induces c-fos in PC12 cells and that this effect is enhanced in the presence of peripherally active BZDs9. Chronic depolarization of PC12 cells due to an increased extracellular potassium concentration has also been shown to influence neurite growth in a calciumdependent manner^{12,13} and to induce c-fos expression^{10,11} (Fig. 1). Thus, we asked whether NGF and elevated K⁺ induce c-fos via the same mechanism. Figure 1 shows that the superinduction of c-fos by NGF plus benzodiazepine is independent of extracellular calcium, as is NGF induction of c-fos (Fig. 2b).

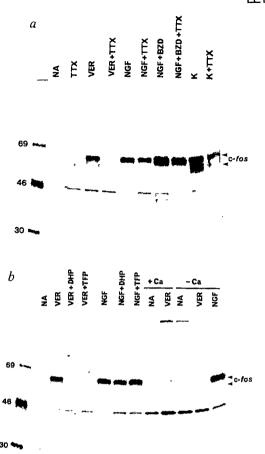

Fig. 2 Veratridine-mediated depolarization induces synthesis of c-fos protein. a, PC12 cells were incubated in methionine-free DMEM with the following additions: no addition (NA), 3 µM tetrodotoxin (TTX), 200 μM veratridine (VER), 200 μM veratridine plus 3 μ M TTX, 200 ng ml⁻¹ nerve growth factor (NGF), 200 ng ml⁻¹ NGF plus 3 μ M TTX, 200 ng ml⁻¹ NGF plus 100 μ M benzodiazepine (7-3351) (NGF+BZD), 200 ng ml⁻¹ NGF plus 100 µM benzodiazepine (7-3351) plus 3 µM TTX (NGF+ BZD+TTX), 50 mM potassium (K), or 50 mM potassium plus 3 μM TTX (K+TTX) for 30 min before labelling with methionine. b, PC12 cells were incubated in methionine-free DMEM containing: no additions (NA), 200 µM veratridine (VER), $200\,\mu M$ veratridine plus $15\,\mu M$ dihydropyridine (nisoldipine) (VER+DHP), 200 µM veratridine plus 15 µM trifluoperazine (VER+TFP), 200 ng ml⁻¹ NGF, 200 ng ml⁻¹ NGF+15 µM dihydropyridine (NGF+DHP), or 200 ng ml⁻¹ NGF plus 15 μM trifluoperazine (NGF+TFP); in basal medium with: no additions (NA), or 200 µM veratridine (VER) in the presence of 1.1 mM calcium chloride (+Ca); and in basal medium with no additions (NA), $200 \,\mu\text{M}$ veratridine (VER) or $200 \,\text{ng ml}^{-1}$ NGF in the absence of calcium (-Ca). ³⁵S-methionine labelling, preparation of cell lysates, immunoprecipitation and SDS-PAGE were as described in Fig. 1 legend. The numbers on the left indicate the Mrs of marker proteins. Arrows indicate the position of the c-fos protein. Tetrodotoxin, nisoldipine and trifluoperazine were added 5 min before incubation with the other agents.

In contrast, elevated potassium induces c-fos only when calcium is present in the extracellular environment (Fig. 1); this suggests that depolarizing concentrations of potassium induce c-fos by provoking an influx of calcium ions, presumably via voltage-dependent calcium channels. This interpretation is supported by the finding that the 1,4-dihydropyridine calcium channel antagonist nisoldipine (DHP)¹⁴ completely blocks potassium-induced c-fos expression (Fig. 1), consistent with the known ability of nisoldipine to block potassium-stimulated calcium uptake into PC12 cells¹⁵. In contrast, the induction of c-fos

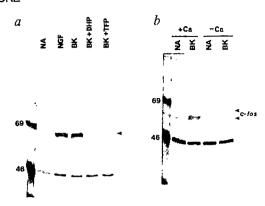

Fig. 3 Stimulation of c-fos expression by the calcium channel agonist BAY K 8644. a, PC12 cells were incubated in methionine-free DMEM containing: no additions (NA), 200 ng ml⁻¹ NGF, 300 nM BAY K 8644 (BK), 2.5 μM BAY K 8644 plus 15 μM dihydropyridine (nisoldipine) (BK+DHP) or 2.5 μM BAY K 8644 plus 15 μM trifluoperazine (BK+TFP). b, PC12 cells were incubated in basal medium with either no additions (NA) or 2.5 μM BAY K 8644 (BK) in the presence (+Ca) or absence (-Ca) of 1.1 mM calcium chloride. The numbers on the left indicate the M_rs of marker proteins. Arrows indicate the position of the c-fos protein. Nisoldipine and trifluoperazine were added (where indicated) 5 min before incubation with the other agents. BAY K 8644 (methyl 1,4-dihydro-2,6-dimethyl-3-nitro-4-(2-trifluoromethylphenyl)-pyridine-5-carboxylate) was synthesized by the research division of Hoffmann-La Roche Inc.

protein (NGF+DHP, Fig. 2b) and mRNA (data not shown) by NGF is insensitive to dihydropyridine treatment.

The depolarization-induced calcium influx (via the voltagedependent calcium channels) appears to elicit c-fos expression by an interaction with calmodulin since chlorpromazine (CPZ), a calmodulin antagonist¹⁶, blocks the action of elevated potassium (see Fig. 1, 50 mM K+CPZ). This notion was further corroborated using another calmodulin inhibitor, trifluoperazine (TFP)¹⁶, which also blocks K⁺-induced c-fos expression (data not shown). These agents did not reduce the level of c-fos after treatmenet with either NGF or 12-O-decanoylphorbolmyristic acetate (PMA) (data not shown). As PMA presumably acts via protein kinase C17, the lack of effect of either CPZ or TFP on this response suggests that the drugs are targeting calmodulin and not protein kinase C, their alternative site of action 18. The more specific calmodulin inhibitor W7 (N-(6-aminohexyl)-5chloro-1-naphthalenesulphonamide¹⁹) clearly veratridine-induced c-fos expression but did not affect NGF induction of c-fos (data not shown). Thus, the available evidence points to calmodulin having a role as a mediator in the coupling mechanism of one group of inducers. These observations emphasize further the mechanistic dichotomy between induction of c-fos by NGF and by elevated potassium.

An alternative method of depolarizing PC12 cells is to use the alkaloid veratridine which holds voltage-dependent sodium channels in their open state^{20,21}. Veratridine, like elevated potassium, provokes an induction of c-fos in a dose-dependent manner (Fig. 2a (VER), and data not shown). This action of veratridine is mediated by the well-characterized adult form of the voltage-dependent sodium channel as it is antagonized by tetrodotoxin (TTX)²² (see Fig. 2a). It has been reported that PC12 cells do not exhibit voltage-sensitive sodium currents in the absence of NGF²³. Thus, our data may have two interpretations. First, this may reflect a fundamental difference between the PC12 cells in various laboratories. Second, PC12 cells may contain a class of TTX-sensitive sodium channels that can be activated only by veratridine. We noted that tetrodotoxin blocks veratridine-induced c-fos expression and is much less effective at reducing the level of c-fos observed following treatment with NGF or other agents, thus precluding a nonspecific inhibition

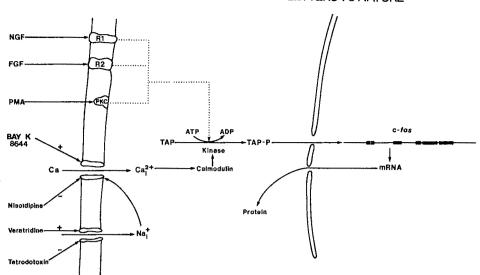

Fig. 4 Schematic representation of the molecular events involved in c-fos induction. The figure includes a summary of the data presented in Figs 2 and 3. The action of ion-channel agonists (+) and antagonists (-) is indicted.

(Fig. 2a). Veratridine stimulation of c-fos expression, like that of elevated potassium, is also calcium-dependent and is blocked by both nisoldipine and antagonists of calmodulin (Fig. 2b). Thus, depolarization of PC12 cells, either by abolishing the ion gradient for potassium or by specifically holding voltage-dependent sodium channels in their open state, results in c-fos induction. The second-messenger coupling mechanism is the same in both instances and seems to involve activation of voltage-dependent calcium channels with a subsequent interaction of calcium with the calmodulin system.

The next question to be addressed is whether the opening of calcium channels alone can lead to induction of c-fos. This proposition was tested using the calcium channel agonist BAY K 8644 (ref. 24), which stimulates calcium uptake in PC12 cells²⁵ and is a potent inducer of c-fos expression in these cells; at a concentration of 300 nM, it elicits the same response as 200 ng ml⁻¹ of NGF (see Fig. 3a). Stimulation of c-fos expression by BAY K 8644 occurs only in the presence of extracellular calcium (Fig. 3b) and is blocked by both nisoldipine and the calmodulin inhibitor trifluoperazine (Fig. 3a). Thus, the action of BAY K 8644 mimics that of extracellular potassium and veratridine treatment both qualitatively and quantitatively. It has been demonstrated recently that BAY K 8644 opens only a limited population of voltage-dependent calcium channels (the so-called long-term or L channels) in dorsal root ganglion neurones²⁶; this suggests that a very specific gated calcium signal is responsible for c-fos activation.

The data presented here demonstrate a close link between the biophysical processes involved in neuronal excitation and gene transcription. In particular, the results show that agents or conditions that modify the open time of voltage-dependent calcium channels can modulate expression of the fos protooncogene. Figure 4 depicts a model of the sequence of events that couple these agents to the transcriptional activation of c-fos. Depolarization of PC12 cells with elevated potassium or veratridine results in prolonged opening of voltage-dependent calcium channels, based on three lines of evidence. First, both of these agents require extracellular calcium to induce c-fos. Second, both veratridine- and potassium-induced c-fos expression are blocked by voltage-dependent calcium channel antagonists such as nisoldipine. Third, a known agonist for the voltage-dependent calcium channel, BAY K 8644, induces c-fos directly. Thus, while veratridine and potassium influence the movement of several ionic species across the plasma membrane, the opening of the calcium channel is the common denominator in the cascade of events that result in c-fos induction. Activation of the voltage-dependent calcium channel then leads to an influx of calcium ions. This supposition is based on the fact that veratridine, elevated potassium and BAY K 8644 all require extracellular calcium in order to induce c-fos. Thus, activation of the voltage-dependent calcium channel must lead to an increase in intracellular calcium to trigger c-fos induction.

All three agents activate calmodulin either as a direct effect of increased calcium levels or by some other indirect route. Calmodulin is implicated because both trifluoperazine and chlorpromazine block c-fos induction by veratridine and potassium. As induction by BAY K 8644 is also blocked by calmodulin inhibitors, calmodulin must be involved at a step subsequent to calcium channel activation. Following stimulation of calmodulin, we propose that there is a calmodulin- or calmodulin kinase-mediated modification of a transcription activating protein (TAP). This modified factor then acts, directly or indirectly, to stimulate c-fos transcription. Although the latter two steps are speculative there is some evidence to suggest that the c-fos gene has an enhancer element which can be activated in trans by inducible factors (ref. 27 and T.C., unpublished data). The existence of a similar agent for the haemoglobin gene has been demonstrated in nuclei of stimulated erythroid precursor cells²⁸. In addition, calmodulin has recently been implicated in the control of the prolactin gene²⁹.

Previously, prompted by observations of c-fos induction by polypeptide mitogens, a number of investigators suggested that c-fos plays a part in controlling cell cycle events. Since then it has been demonstrated that c-fos induction is not restricted to a particular phase of the cell cycle and is not necessarily associated with mitogenesis^{7,30,31}. Indeed, in some systems c-fos expression has been associated with cellular differentiation^{8,9,11,32}. Our own studies on PC12 cells led us to propose a more general role for c-fos in coupling early events associated with receptor occupation (such as phosphorylation, methylation and ion flux) to long-term changes in gene expression⁹. We have now confirmed and extended these data to include an independent biochemical pathway for c-fos induction that appears to be particularly prevalent in neuronal cells, and which involves a gated calcium signal. The induction of c-fos seems to be associated with, and is a genetic harbinger for, a change in state of many cell types. The change in state may be from quiescence to proliferation or from less to more differentiated for example. We suggest that the target genes for c-fos are different in the many and varied situations in which induction occurs. We have shown that agents that classically depolarize neurones lead to an induction of c-fos by a gated calcium signal. Thus, we propose that c-fos and its co-regulated genes are excellent candidate genes for coupling excitation of the neurone to long-term adaptive modifications of transcription.

Tumour induction by the retinoblastoma mutation is independent of N-myc expression

Jeremy Squire*, Audrey D. Goddard*, Marc Cantont, Andrew Becker‡, Robert A. Phillips* & Brenda L. Galliet

Departments of * Medical Biophysics, † Ophthalmology and ‡ Medical Genetics, University of Toronto, and † The Hospital for Sick Children, 555 University Avenue, Toronto, Canada M5G 1X8

Retinoblastoma (RB) tumours form in the eyes of young children when homozygosity for a mutation at the Rb-1 locus develops in a somatic retinal cell^{1,2}. A similar shift to homozygosity for the RB mutation has been observed in osteogenic sarcoma (OS) tumours that commonly arise as second tumours in children who survive RB3. This observation suggests that the Rb-1 locus controls the expression of genes with oncogenic potential; a possible target is the oncogene N-myc, which is sometimes amplified and overexpressed in the neuroectodermal tumours neuroblastoma⁴⁻⁷ and RB⁵⁻⁸. However, N-myc is developmentally regulated in normal murine embryogenesis9, and an alternative possibility is that the expression of the gene in tumour cells reflects their embryonic origin and is unrelated to the RB mutation. We have therefore examined N-myc expression in various fetal, adult and tumour tissues, and report here that the gene is expressed in fetal but not in adult brain and retina and in near-diploid RB tumour samples at levels similar to those observed in normal fetal retina. Only RB tumours with genomic amplification of the N-myc gene exhibited increased levels of expression; and no N-myc transcripts were detected in osteogenic sarcomas initiated by mutations at the Rb-1 locus³. We therefore conclude that the expression of N-myc in RB tumours probably reflects the origin of the tumour from an embryonic tissue normally expressing the gene and is not directly associated with the mutation at the RB locus.

The Rb-1 locus may have a regulatory function like that of the diploid regulatory/suppressor genes postulated by Comings to control expression of other genes¹⁰. In the absence of the normal RB gene product, such target genes may lead to malignancy because they continue to be expressed at inappropriate levels. N-myc is a developmentally regulated proto-oncogene which is a candidate for regulation by a tumour suppressor gene like the RB gene. N-myc is normally expressed in the early stages of development in multiple differentiation pathways Differentiation of neuroblastoma¹¹ and teratocarcinoma cells⁹ in culture is accompanied by a decrease in the level of N-myc

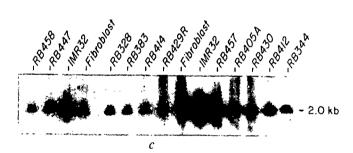

Fig. 1 Southern blot analyses of 17 RB tumours or cell lines and one osteogenic sarcoma cell line (OS234) probed with N-myc. DNA was extracted from 5×10^7 - 10^8 cultured cells or tumour cells or tumour material by the standard method of phenol and isoamyl alcohol extraction, followed by ethanol precipitation²⁴. DNAs (10 µg) were digested with EcoRI (Boehringer Mannheim) using conditions recommended by the supplier. Digested genomic DNA was separated by gel electrophoresis in 0.8% agarose, and blots were made onto nitrocellulose membrane²⁵. The recombinant plasmid pNB-1 (N-myc)⁵ was labelled with 32 P-dCTP by nick-translation²⁶ to a specific activity of 3×10^8 c.p.m. μ g⁻¹. Washing of filters after probing was carried out in either high-stringency conditions $(0.1 \times SSC, 0.2\% SDS, 65 ^{\circ}C)$ (a) or conditions of moderate stringency $(1 \times SSC, 0.1\% SDS, 65 ^{\circ}C)$ (b, c). The blots were reprobed with pESD14.1.1 (ref. 18) to control for the amount of DNA loaded per lane, and then transferred to the filter. The resultant ratios between the two signals were compared for all lanes except RB375A, RB475D, RB458 and RB447; the average ratio was Nmyc/ESD = 0.84:1.0, with a range of 0.21-2.00, indicative of no amplification. a, RB355-7 is a subclone of RB355. This filter was washed to show the relative copy numbers of N-myc. Fibroblast DNA was used as a diploid control. b, c, Several RB samples and one osteogenic sarcoma (OS234). IMR32 and RB355 are positive controls for N-myc-amplification; fibroblast DNA is a diploid control. DNA sources are as follows (1) Fresh tumour material: RB475-A and -D (from separate eyes of one patient), RB493, RB458, RB457 and RB328. (2) Tumour cell culture: OS234, RB383, RB429R, RB405-A, RB430, RB344 and IMR32. (3) RB tumour cell culture derived from xenografts: RB355, RB355-7, RB412, RB409, RB247, RB447 and RB414.

Table 1 Relative levels of N-myc genomic amplification and mRNA in nine RB tumours, fetal retina, two OS tumours and control cell lines

				Level of N- relative to	myc RNA relative to
Cells	Source	DM/HSR	DNA	β -tubulin	ESD
Y79-T	С	+	40×	69×*	4×
IMR32	C	+	20×	120×*	NT
RB355	MC	+	35×	13×*	NT
RB409	MC	-	1×	1.0×	1.0×
RB344	C	-	1×	1.2×	NT
RB247C	MC	-	1×	1.1×	NT
RG412	MC	-	1×	0.48×	NT
RB447	MC		1×	Present†	NT
RB430	С	_	1×	0.81×	NT
RB430	S	-	1×	NT	1.9×
RB517	S	-	1×	NT	1.9×
Fetal retina	S	NT	NT	0.32×	1.6×
Adult retina	S	NT	NT.	NT	< 0.05
Fetal brain	S	NT	NT	NT	0.27‡
Adult Brain	S	NT	NT	NT	< 0.05
OS108	M	-	1×	NT	< 0.05
OS234	M	+	1×	NT	< 0.05
HL60	C	+	NT	< 0.05	< 0.05
HeLa	С	-	NT	< 0.05	NT
Fibroblast	С	NT	1×	NT	NT

Tumour samples were obtained from three sources: S, surgical specimen; M, grow in nude mice; C, grown in vitro. Where there are two letters, the last letter indicates the source of tumour cells studied and the preceding letter indicates the culture history of the tumour cells; for example, MC indicates that the tumour was grown in xenografts in nude mice before passage to tissue culture. The presence of double minute (DM) or homogeneous staining regions (HSR) was tested on G-banded karyotype preparations. DNA copy number is given relative to single-copy fibroblast hybridization on Southern blots (Fig. 1). Relative levels of DNA and RNA were estimated by grain density using a BioRad 620 video densitometer and BioRad Model 3392A integrator. N-myc RNA levels were normalized with respect to β -tubulin¹⁷ or ESD¹⁸ signals. RB409 N-myc expression was assigned an arbitrary value of 1.0 as it was present on all Northern blots analysed. NT, not tested.

- * An approximation because the signal was beyond the linear response region of the film.
 - † Densitometry was not done on this blot.
 - ‡ Densitometry done using the longer exposure (see Fig. 2b).

expression, suggesting that regulatory mechanisms for N-myc are intact in these malignant cells. Genomic amplification of N-myc is restricted primarily to neuroectodermal tumours^{4,6-8,12,13}, and many correlate with poor clinical prognosis^{14,15}.

We studied genomic amplification of N-myc in 17 RB tumours (Fig. 1) and 2 OS cell lines derived from second primary malignancies in patients who had previously had RB (one OS tumour not shown). N-myc amplification was found in only one of 17 RB tumours, RB355¹², and in neither OS line despite cytological evidence of gene amplification. The known N-myc amplification in the neuroblastoma line IMR32⁵, and in the long-established RB line Y79 ^{7,16}, were used as positive controls. No rearrangements of N-myc were detected.

Nine RB tumours were examined for levels of N-myc expression using Northern blotting techniques. Seven RB tumours were studied after culture or xenografts, one directly from the surgical specimen (RB517) and one from both the surgical specimen and tissue culture (RB430). RB517 has a consitutional deletion at chromsome band 13q14. The presence of intact RNA on the Northern blots was determined by probing sequentially with N-myc and β -tubulin¹⁷ or concurrently with N-myc and a complementary DNA clone of the esterase D (ESD) gene¹⁸ (Fig. 2). ESD and β -tubulin are constitutively expressed¹⁹. All RB tumours expressed the expected major 4.0-kilobase (kb) transcript of the N-myc gene⁵. Fresh RB tumours expressed levels of the N-myc transcript comparable to those

in RB samples from cell lines or xenografts and fetal retina (Fig. 2; Table 1). RB430 was examined both as a fresh surgical specimen and after tissue culture for 3 years, and no change in N-myc expression was observed. Both RB tumours with genomic amplification, Y79 and RB355, and the neuroblastoma line IMR32, expressed N-myc at high levels. Expression of N-myc was not detected in HeLa cells or in the promyelocytic leukaemia cell line HL60. No N-myc signal was observed even when HL60 was overloaded in the Northern blot.

The cells of origin of RB have not yet been identified, but are probably the embryonic cells of the fetal retina²⁰. Therefore, we collected fetal retinas at weeks 6-10 of gestation, and pooled them for use as a source of RNA. We found that N-myc was expressed at equivalent levels in fetal retina, in the RB tumours without genomic amplification of N-myc, and in fresh RB tumours (Table 1). We suggest that the presence of N-myc messenger RNA in RB tumours is a consequence of the normal expression of this gene in the retinal precursor cells which transform into RB tumours. It is difficult to determine whether there is cellular heterogeneity in the specimens of fetal retina used since, morphologically, all of the cells in the retina have a similar appearance at this stage of development. The observation that the level of N-myc expression in fetal retina was equivalent to the level in pure populations of RB tumour cells is consistent with the conclusion that the fetal retinal specimen was not significantly contaminated with other cells. In fact, most retinal cells at this early developmental time may be potential precursors for RB tumour development. Alternatively, at this gestational stage all retinal cells, whether potential retinoblastoma precursors or not, may express N-myc transcripts. The lack of N-myc transcripts in adult retina indicates that N-myc expression is regulated during the differentation of the retina and that the terminally differentiated cells no longer express the gene. Loss of the normal alleles at the Rb-1 locus may prevent the normal differentiation of the fetal retinal cell involved in transformation, and thus N-myc expression may be maintained at embryonic levels of expression.

Fetal brain showed a low level of N-myc expression when the Northern blots were exposed more intensely (Fig. 2b). This low level is not surprising in view of the reported N-myc heterogeneity observed in fetal brain in early development²¹. On the Northern blot shown in Fig. 2, the adult brain sample was underloaded but did not give a signal for N-myc even in the more intense exposure, when control ESD transcripts were detectable (Fig. 2b). We conclude that N-myc expression is regulated during development of the brain, as has been shown in mouse brain²¹.

Patients with bilateral RB tumours are reported to have a predisposition to develop specific second malignancies, most commonly osteosarcomas, subsequent to and independent of the initial RB tumour²². Reduction to homozygosity in the region of the Rb-1 locus also occurs in osteogenic sarcoma, indicating that recessive mutations of this gene are involved in the induction of osteosarcoma and retinoblastoma³. OS234 and OS108 are second tumours from RB patients; OS108 has been shown to reduce to homozygosity at chromosome 13³. The critical test for an intimate relationship between N-myc and the Rb-1 mutation is the expression status of N-myc in the osteosarcomas of RB patients. Neither OS tumour studied was expressing N-myc (Fig. 2). Therefore, we conclude that Rb-1 mutations can lead to malignancy without the overexpression or deregulation of N-myc.

Two other groups have studied N-myc expression in RB tumours. Lee et al.⁸ compared N-myc RNA levels in RB tumours with those in one human fetal retina of undefined gestational age and in one bovine adult retina. They detected N-myc expression only in the tumours, and concluded that N-myc was abnormally highly expressed in RB tumours and suggested that this gene could be the regulatory target of the RB gene. Schwab et al.⁶ detected no N-myc expression in three cell lines derived

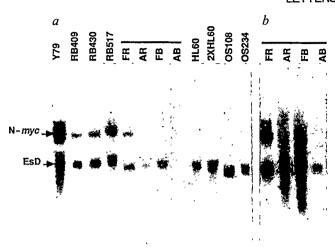

Fig. 2 Northern blot of two RB tumour cell lines (Y79, RB409), two fresh RB tumours (RB430, RB517), fetal (F) and adult (A) retina (R) and brain (B), two OS tumours (OS108 and OS234), and one promyelocytic leukaemia cell line (HL60). Total cellular RNA was prepared by guanidine thiocyanate-caesium chloride gradient centrifugation²⁷. Poly(A)⁺ RNA was obtained by oligo(dT)-cellulose chromatography. N-myc and pESD14.1.1 (ref. 18) were radiolabelled as described in Fig. 1 legend and simultaneously hybridized to GeneScreen membrane according to the method of Church and Gilbert 28 . ESD served as an internal control for the presence of intact mRNA. 25 μg of total RNA was loaded per lane, except for three lanes: 50 μg of total RNA for 2×HL-60; and 2 µg of poly(A)+RNA for fetal retina and for OS108. a, 22-h exposure at room temperature with no intensifier; b, 19-h exposure at -70 °C with an intensifier.

from RB surgical specimens, but several observations in our laboratory suggest that these lines may have originated from the non-RB component of the surgical specimen: two of the cell lines do not have any of the cytogenetic abnormalities characteristic of RB tumours²³, fail to stain with a monoclonal antibody that reacts positively with all other RB tumours and lines, and do not resemble RB tumours in suspension tissue culture.

The expression of N-myc RNA in normal fetal retina and in RB tumours suggests that N-myc is a normal product in developing retina. The RB cell lines that do develop genomic amplification of N-myc may gain proliferative advantage by means of the accompanying excessive expression of N-myc, a gene normally functioning in the cells from which RB tumours arise. It is possible that N-myc is not normally expressed in the bone cells in which homozygosity for the RB mutation leads to OS tumours. Consequently, no N-myc transcripts are observed in the OS tumours. We have clearly demonstrated equal levels of expression of N-myc in RB tumours and in normal fetal retina, and that N-myc is not expressed in the OS tumours induced by the RB mutation. Thus, expression of N-myc cannot be essential to the initiating malignant process in these tumours.

We acknowledge the help from Wendy Holmes, Joan Cocking and Joan Chin in culturing RB tumour cells, and thank Dr J. M. Bishop for the N-myc probe and Dr D. W. Cleveland for the β -tubulin probe. Discrete cis-active genomic sequences dictate the pituitary cell type-specific expression of rat prolactin and growth hormone genes

The anterior pituitary gland, which is derived from a common primordium originating in Rathke's pouch, contains phenotypically distinct cell types, each of which express discrete trophic hormones: adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), prolactin, growth hormone, and follicle stimulating hormone (FSH)/luteinizing hormone (LH) (reviewed in ref. 1). The structurally related prolactin and growth hormone genes, which are evolutionarily derived from a single primordial gene2, are expressed in discrete cell types-lactotrophs and somatotrophs, respectively—with their expression virtually limited to the pituitary gland1. The pituitary hormones exhibit a temporal pattern of developmental expression with rat growth hormone and prolactin characteristically being the last hormones expressed3-8. The reported co-expression of these two structurally related neuroendocrine genes within single cells prior to the appearance of mature lactotrophs, in a subpopulation of mature anterior pituitary cells, and in many pituitary adenomas 1,6-9 raises the possibility that the prolactin and growth hormone genes are developmentally controlled by a common factor(s). We now report the identification and characterization of nucleotide sequences in the 5'-flanking regions of the rat prolactin and growth hormone genes, respectively, which act in a position- and orientation-independent fashion to transfer cell-specific expression to heterologous genes. At least one putative trans-acting factor required for the growth hormone genomic sequence to exert its effects is apparently different from those modulating the corresponding enhancer element(s) of the prolactin gene because a pituitary 'lactotroph' cell line producing prolaction but not growth hormone selectively fails to express fusion genes containing the growth hormone enhancer sequence.

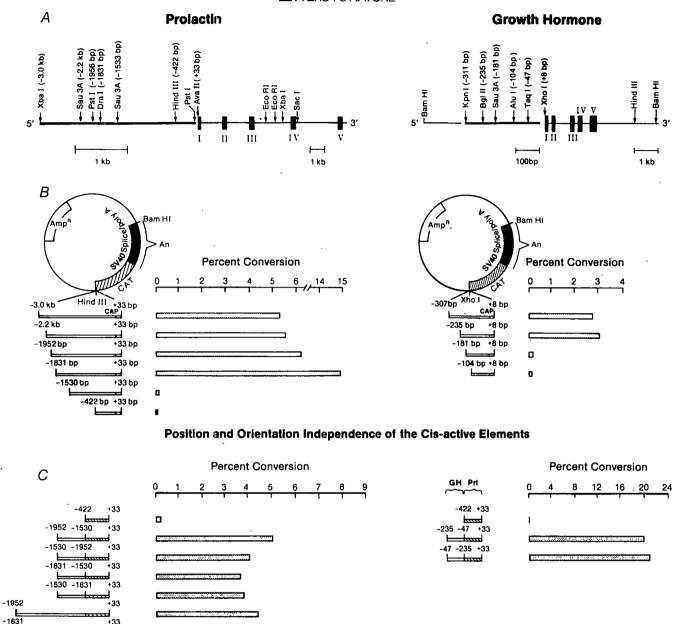

Fig. 1 Identification of cis-active region(s) in the 5' flanking prolactin and GH genomic sequences which confer cell-specific expression. A, Activity of rat prolactin genomic, CAT fusion constructions. The sites used for the constructions are listed on the map of the rat prolactin and growth hormone genes, based on previous reports. Fragments of the indicated sizes, each utilizing a common. 3' end (+33 for prolactin, +8 for growth hormone) were ligated into pSV2 CAT such that the promoter and CAP site were contributed by the prolactin or growth hormone genomic fragments. No viral enhancers were present in the final construction. B, Sites used for deletional analysis are indicated, and the diagrammed fusion genes were transfected into rat pituitary cell lines (GH4, G/C). Mapping the cis-active genomic sequences for each gene was accomplished using expression of a reporter gene, bacterial CAT¹⁵, in GH4 cell lines, assessed in cells harvested 48 h after transfection. Results are the average of duplicate determinations differing by <5% of 3-12 experiments in GH4, G/C, and GH3 cell lines. All data were significant (P <0.001). C, Position- and orientation-independence of the rat prolactin and GH genomic enhancer sequences. A 188-bp GH genomic sequence (-235 to -47) was placed in both orientations 5' to a gene containing the prolactin promoter fused to the CAT gene (the Prl-422 CAT construction) and used to transfect GH4, cells in three experiments of similar design. Prolactin genomic fragments (-1,831 to -1,532) and (-1,952 to -1,532) were fused in both orientations to the Prl-422 CAT construction. Transfections were performed in GH4 cells. In additional experiments, the -235 to -47 and -1,831 to -1,532 regions of the growth hormone and prolactin genes, respectively, were placed in both possible orientations 3' of the CAT transcription unit, located approximately 350 bp 3' of the poly(A) site in the Prl-422 CAT construction. Even in the inverted (3' to 5') orientation, these constructions

Methods. The fusion genes containing the GH fragments diagrammed above were constructed by converting the HindIII site in pSV2 CAT to an XhoI site and ligating GH 5' flanking fragments into the BamHI, XhoI sites of the vector. 5' GH sites were converted to BamHI sites following filling using T4 polymerase for the KpnI site, or ligating into the BamHI in the case of BgIII and SauIIIA's sites, using conventional techniques, and placing these fragments into PSV2 CAT, as diagrammed. In the case of the prl/CAT fusion genes, an AvaII site 33 nucleotides 3' to the CAP site was converted to a HindIII site and indicated 5' sites (XbaI, PstI, DraI, SauIIIA) were either converted to Bam HI sites using T4 polymerase-catalysed fill reactions where appropriate or ligated into the BamHI site (SauIIIA). The vector containing the HindIII to AvaII (-422 to +33) fragment of the prolactin gene fused to the CAT gene is referred to as Prl-422 CAT. In addition to the diagrammed constructions, a 5' flanking GH sequence extending -7 kb (using an EcoRI site) and an XhoI to BamHI fragment encompassing the entire coding portion and 2.7 kb of 3' flanking GH genomic sequences ligated in opposite orientation 5' to the Prl-422 CAT fusion gene were tested; these constructions did not exhibit enhancer function.

To ascertain the existence of genomic regions that determine pituitary-specific gene expression, fusion genes containing 3 kilobases (kb) or 235 base pairs (bp) of prolactin or growth hormone genomic 5'-flanking sequences, respectively, were fused to a reporter gene encoding bacterial chloramphenicol acetyltransferase (CAT) (Fig. 1) and introduced into a series of heterologous cell lines. As shown in Table 1, the fusion genes are expressed only in prolactin and growth hormone-producing pituitary cell lines (GH₄, G/C).

The growth hormone and prolactin cis-active elements responsible for cell-specific expression were characterized by generating a series of deletions extending from -3 kb to -172 bp in the 5' flanking prolactin genomic sequences (Fig. 1A) and from -2 kb to -104 bp of the 5' flanking growth hormone genomic sequences (Fig. 1A). In the case of the prolactin genomic sequences, enhanced expression of the CAT gene product was observed with sequences extending 1.83 kb 5' of the prolactin gene transcription initiation (CAP) site, and was virtually eliminated with deletion to -1.53 kb, although a small residual enhancement was observed with 5' flanking fragments as short as 172, but not 70, base pairs. In the case of growth hormone 5' flanking genomic sequences, maximally enhanced expression of the reporter gene was observed in constructions containing >235 base pairs of 5' flanking information, while deletion to -181 base pairs 5' of the CAP site virtually abolished expression of reporter function in these cells (Fig. 1B).

As shown in Fig. 1C, both prolactin and growth hormone genomic fragments extending from -1.95 or -1.83 to -1.53 kb and from -235 to -47, respectively, fused to a 422-bp prolactin gene promoter region resulted in marked stimulation of the expression of the fusion genes in the growth hormone-producing cells, irrespective of orientation or position. The prolactin or growth hormone cis-active elements enhanced reporter gene expression even when placed 3' of the reporter gene (Fig. 1G). Primer extension analysis confirmed correct CAP site usage in both the prolactin and growth hormone constructions (Fig. 2).

The prolactin and growth hormone cis-active sequences acted in a cell-specific manner independent of possible transcriptional restriction imposed by their respective promoters. Chimaeric genes containing either the prolactin genomic fragment from -1.83 kb to -1.53 kb or the growth hormone genomic fragment from -235 bp to -47 bp ligated to a herpes thymidine kinase (tk) promoter, CAT gene fusion resulted in no enhancement of gene expression in heterologous cell types, while expression of these chimaeric genes in GH₄ and G/C cell lines was markedly enhanced (Fig. 1C). The possibility that a restriction in tissuespecific expression was imposed by the prolactin promoter itself is unlikely because the prolactin promoter (-422 to +33) was efficiently expressed in fibroblasts and CV1 cells in the presence of the simian virus 40 (SV40) enhancer (Table 1). Despite the 2.5- to 3.5-fold increase in expression of constructions containing the -1.83 kb compared to -1.95 kb 5'-flanking prolactin genomic fragment (Fig. 1B), the presence of a biologically important suppressor or silencer sequence appears less likely because both the -1.95 to -1.53 and -1.83 to -1.53 kb fragments exerted comparable effects when inserted in front of the prolactin genomic promoter extending to -422 bp (Fig. 1C).

Based on these analyses, we conclude that a 298-bp sequence located approximately 1.85 kb upstream of the prolactin gene CAP site, and a 188-bp sequence located approximately 200 bp upstream of the growth hormone gene CAP site, act as enhancers in the GH cells and appear to be critical for the tissue-specific expression of these genes.

More detailed analyses were performed to identify the minimal sequences in the prolactin and growth hormone genes sufficient for enhancer function. As diagrammed in Fig. 3, a series of genomic fragments inserted in front of the prolactin promoter, CAT fusion gene (the -422 to +33 fragment, the plasmid referred to as Prl-422 CAT, Fig. 1) were tested for ability to confer enhanced expression of the reporter gene.

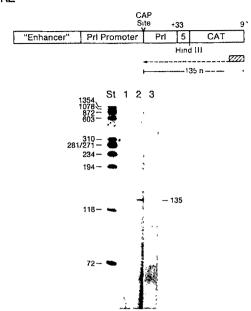

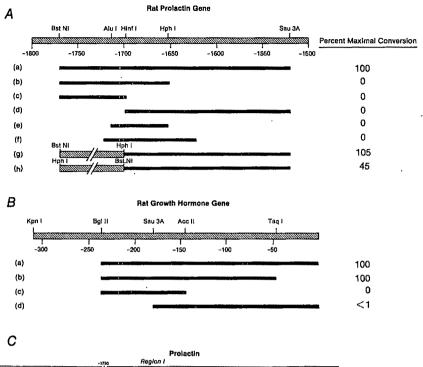

Fig. 2 Mapping the transcription initiation sites of the chimaeric genes containing the prolactin and growth hormone enhancer elements. Chimaeric genes containing the growth hormone or prolactin cis-active elements (-235 to -47 and -1,952 to -1532, respectively), fused to the Prl-422 CAT fusion gene, as described in Fig. 1C, were transfected into GC2 cells, and RNA was prepared and subjected to primer extension analysis, as described under methods. As diagrammed in A, for both constructions, the expected primer extension product was 135 nucleotides if the expected prolactin gene CAP site was utilized. B. The primer extension products using RNA from cells transfected with: lane 1, the prolactin -1,952 to -1,532, Prl-422 CAT fusion gene, from which the prolactin promoter region (-422 to -33) was removed. No CAT activity was detected in cells transfected with this construction; lane 2, the prolactin -1,952 to -1,532, Prl-422 CAT fusion gene; lane 3, the growth hormone -235 to -47, Prl-422 CAT fusion gene. Standards are the HaeIII digests of ΦX174 DNA. Autoradiograph shown was developed following a 7-day exposure

Methods. Total RNA was isolated from GC₂ cells 48 h following transfection with 10 µg plasmid DNA per plate, by homogenization in thiocyanate and pelleting through cesium chloride to remove DNA. A single-stranded primer of sequence 5' GTTCTTTAC-GATGCCATTGGGATATATCAACGG 3' complementary to nucleotides 29-61 of the CAT coding sequence, was labelled on the 5'-terminus to a specific activity of 10^9 c.p.m. μg^{-1} using T_4 polynucleotide kinase and $(\gamma^{-32}P]ATP$ (7,000 Ci mmol⁻¹. ICN). For each reaction, 50 µg total RNA and 3 ng labelled primer were heated to 70 °C in 12 µl RT buffer (50 mM Tris pH 8.0, 8 mM MgCl₂, 50 mM KCl, 40 mM dithiothreitol) and slowly cooled to 55 °C. The annealed primer and RNA were then precipitated with 0.3 M sodium acetate and 1 volume of isopropanol and resuspended in RT buffer. dATP, dCTP, dGTP and dTTP were added, to a final concentration of 1 mM each in a final volume of 20 µl. The reaction was initiated with 24 units of reverse transcriptase and allowed to proceed for 30 min at 42 °C. After phenol/chloroform extraction, the extension products were analysed on 8% denaturing polyacrylamide gels.

Deletion of 61 5' nucleotides of the 298-bp prolactin enhancer element (-1,831 to -1,769) resulted in no loss of activity (Fig. 3 (a)); however, dividing the region by cleavage at a *HinfI* site at nucleotide -1,698 resulted in virtually complete loss of activity of both of the resultant fragments (Fig. 3 (c), (d)), apparently splitting a critical site or separating two discrete sequences. To test the possibility that a critical site was split, regions extending both 5' and 3' of the *HinfI* site were tested. Neither a 50-bp sequence (-1,713 to -1,663), nor a 98-bp fragment (-1,722 to -1,625) exhibited any enhancer activity (Fig. 3 (e), (f)). Therefore, a fragment containing 106 nucleotides including the 5' sequences known to be sufficient for activity (-1,769 to -1,663) was tested. This region was entirely silent in GH cell lines (Fig.

Fig. 3 Mapping the 5' and 3' limits of the cis-active prolactin and growth hormone genomic sequences specifying cell-specific gene expression. A, A series of prolactin 5' genomic restriction fragments were preepared as diagrammed and placed 5' to the fusion gene Prl-422 CAT, containing the prolactin genomic sequences from -422 to +33 (shown in Fig. 1). These plasmids were used to transfect GH₄, G/C, and 235-1, as described in the legend to Fig. 1. The -1,769 to -1530fragment, which gave a 24±8% conversion in different experiments, represented 100% for the prolactin gene fragment series. Similar results were obtained in five experiments of similar design. The fragment -1,769 to -1,663 exhibited 0% of expression in five separate experiments (GH₄, G/C and 235-1 cell lines); but 15% maximal activity was observed in two separate experiments. B, Growth hormone genomid fragments were tested for their ability to direct CAT expression in GH₄ cells. The -235 to -47 fragment and the -235 to -146 fragment were fused to the prolactin -422 CAT fusion gene. The -235 to -47 fusion gene activity (5-12% conversion in separate experiments) represented maximal activity (100%). C, Sequences of the cellspecific enhancer elements of the rat prolactin and growth hormone genes. The boxed sequences indicate regions which are critical for activity based on deletion mapping in A. There appear to be two functionally separable regions in the prolactin enhancer (Region I and Region II). The growth hormone sequence is based on the data of Barta et al.²⁰. The prolactin genomic sequence was determined for the fragments used in these experiments using dideoxynucleotide, enzymatic sequencing methods²¹, and is in agreement with the recently published data of Maurer¹⁵ except for the identification of residue -1,667

Growth Hormone

as a T. Results shown are the average of three or four separate experiments.

Methods. Prl 5' flanking fragments from BstNI, SauIIIA (-1,769 to -1,530), BstNI, HinfI (-1,769 to -1,695), HinfI, SauIIIA (-1,697 to -1,530), AluI-HphI (-1,713 to -1,663 and BstNI, HphI (-1,769 to -1,663) were inserted into the plasmid Prl -422 CAT using the strategy described in the legend to Fig. 2. The 98-bp fragment extending from -1,722 to -1,625 was constructed by synthesis of two synthetic oligonucleotides using phosphoramidite chemistries (71-mers) corresponding to sense (-1,722 to -1,658) and antisense (-1,691 to -1,625), and including sequences generating a 5' XhoI site and 3' BamHI site, annealing, filling using the Klenow fragment of Escherichia coli polymerase, cleaving with XhoI and BamHI, and inserting into the Prl -422 CAT vector. The final construction involved placing the BstNI to HphI fragment (-1,769 to -1,663) ligated with XhoI linkers, in front of the construction containing the HinfI to SauIIIA fragment (-1,697 to -1,530). All plasmids were purified by two CsCl gradients prior to transfection, which was performed using GH₄, G/C, and 235-1 cell lines. Results are the average of duplicate determinations (50 μg protein, 10 h assays) in three separate experiments. The GH genomic constructions involved ligating an XhoI linker at the AccII site, and inserting the resultant Bg/II, XhoI fragment (-235 to -146) into the Prl -422 CAT construction. Other constructions are described for above.

3 (b)); however, in two experiments with GC₂ cells, approximately 15% of maximal activity was observed, perhaps reflecting altered levels of a required trans-acting factor(s) in some GH cell lines. Based on these data, it appeared possible that there were two separate regions required for prolactin gene enhancer function. This possibility was tested by the ligation in both possible orientations of the inactive 106 nucleotide fragment (-1.769 to -1.663), to the silent region 3' of the HinfI site (-1,697 to -1,530) (see Fig. 3 (g), (h)). Although in five separate experiments neither component fragment alone exhibited any activity, the chimaeric constructions were always active. The fusions in which the two fragments were in the same orientation exhibited 100% of maximal enhancer activity (Fig. 3 (g)), while the chimaeric construction in which the 106 nucleotide 5' fragment was placed in a 3' to 5' orientation exhibited approximately 45% of maximal enhancer activity (Fig. 3 (h)). Inspection of the fusion junctions revealed no fortuitous reconstitution of sequences around the HinfI or HphI sites in either construction.

These data indicate the presence of two discrete, separable sequences, both of which are required for full enhancer function, with no absolute constraints on the relative position or orientation of these two elements for their functional complementation.

Because an 89-bp growth hormone gene region extending from -235 to -146 was insufficient to produce any enhancement, there would appear to be >35 bp spanning the 5' and 3' boundaries of the growth hormone gene enhancer sequence (Fig. 3).

To test the possibility that different factor(s) confer activity characteristic of the respective enhancer elements, the prolactin and growth hormone genes were tested in a rat pituitary cell line (235-1) which produces prolactin but no detectable growth hormone 10. Although the prolactin enhancer is highly active in this cell line, the growth hormone enhancer fails to function even when fused to the prolactin gene promoter (Fig. 4), suggesting different trans-acting factors regulate the two enhancers despite the evolutionary relatedness of the two genes. A chimaeric construction containing the prolactin enhancer

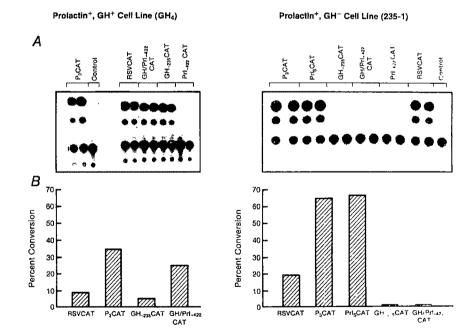

Table 1 Identification of cis-active regions in the 5' flanking sequences of the rat prolactin and growth hormone genes

				Per cent conversi	on
Cell	Species	Type	Prl-5'F	<i>GH</i> -5'F	RSV-EN
MCF7	Human	Mammary epithelium	$\bar{0}$	ō	18
208F	Rat	Fibroblast	ō	$ar{0}$	70
F9	Mouse	Embryonic	ō	$\bar{0}$	50
HIT	Hamster	Pancreatic (endocrine)	$\bar{0}$	$ar{0}$	19

GH₄	Rat	Pituitary (endocrine)	6	4	22
G/C	Rat	Pituitary (endocrine)	11	15	15

Fragments extending from -3 kb to +33 bp of the rat prolactin (PI) gene and from -235 to +8 bp of the rat growth hormone (GH) gene were fused to the HindIII site of the bacterial chloramphenicol acetyl transferase (CAT) gene¹⁵, as diagrammed in Fig. 1, such that the promoter and cap site were contributed by the inserted fragment (referred to as Prl 5'F and GH 5'F, respectively). These constructions, and a comparable construction containing the Rous sarcoma virus (RSV) promoter/enhancer [RSV-EN] were used for DNA mediated gene transfer using a series of cell lines, and the activity of expressed CAT enzyme was quantitated 48 h later; the per cent conversion of ¹⁴C-chloramphenicol to the acetylated form is presented. Results are the average of duplicate determinations differing by <5%, and the results were confirmed for each cell line in 3-15 separate experiments. The average expression \pm s.e.m. for the prolactin and growth hormone fusion genes was $18.2\% \pm 3.5\%$ and $4.3\% \pm 0.8\%$, respectively; results were significant at P < 0.001. In other experiments, RSV CAT recorded up to 45% conversion in MTC-CA cells while Prl 5'F and GH 5'F still gave undetectable signals. SV40 enhancer, promoter and Moloney leukaemia virus (MLV) enhancer, promoter, CAT fusions were also used as controls, confirming efficient transfection into the heterologous cell lines. Function of the prolactin promoter in heterologous cell lines was confirmed by demonstration of reproducibly efficient expression of chimaeric constructions containing SV40 enhancer, prolactin promoter (Prl-422, CAT, Fig. 1) in 208F fibroblasts and CV1 cells (6-8% and 25-30% conversion, respectively). A construction containing the MLV enhancer, prolactin promoter was also expressed in these cell lines. $\bar{0}$ = no detectable conversion above mock transfection.

Methods. Plasmids were constructed as described in the legend to Fig. 1, using a BglII-TaqI (-235 to +8 bp) fragment of the GH gene; and XbaI site (-3 kb) and AvaII sites (+33 bp) of the prolactin gene, and the BamHI and HindIII sites of the vector following appropriate site conversions using synthetic linkers by standard techniques. XhoI and HindIII linkers were added at the XbaI and AvaII sites, respectively, of the prolactin genomic fragment, and the fragment was ligated into the XhoI/HindIII sites of the modified vector pSV2 CAT¹⁵. The HindIII site of pSV2 CAT was converted to an XhoI site prior to the insertion of the GH fragments into the BamHI/XhoI sites. All transfections were performed using 10 μg ml⁻¹ of plasmid DNA and the calcium phosphate co-precipitation method¹⁶ or DEAE-dextran sulphate method¹⁷ 48 h prior to harvest. Chloramphenicol acetyl transferase activity was quantitated using 50 μg of protein extract and 10 h incubations, and subjected to chromatography as previously described¹⁵. The RSV, CAT plasmid construction used has been reported¹⁷. In the assay conditions used, there was a linear relationship between chloramphenicol acetylation and CAT activity. Each cell line was grown in serum-containing medium, and medium was changed 3 h prior to transfection.

Fig. 4 Evidence for discrete trans-acting factors mediating the prolactin and growth hormone enhancers. A rat pituitary cell line of lactotroph origin (235-1)¹⁰, which produces only prolactin was used to assess cell-specific action of the GH and Prl gene enhancer sequences. Plasmids analyzed were the GH (-235 to +8) CAT fusion (GH - 235 CAT), the RSV CAT fusion (RSV CAT), the Prl (-422 to +33) CAT fusion (Prl-422 CAT), and a GH (-235 to -47) fragment inserted into the Prl/CAT fusion gene (GH/Prl-422 CAT), the 3-kb prolactin CAT fusion (P3 CAT), and a fusion gene containing Prl -1,831 to -1,530 ligated to the Prl-422 CAT (Prls CAT), as diagrammed in Figs 1 and 2. A shows the autoradiograph of the CAT assay of the plasmids transfected into GH₄ cells (left) or 235-1 cells (right). B shows the per cent conversion for both cell lines in a different experiment. Results were confirmed in five separate experiments of similar design, using 50 µg protein, 10 h assays as previously described

(-1,831 to -1,530) fused 5' to the 235 bp growth hormone flanking region was analysed for expression in the 235-1 cell line and found to be fully active, indicating the growth hormone promoter region was competent for expression, and that failure to express the growth hormone gene in 235-1 cells reflects the apparent absence of a critical *trans*-acting factor.

Despite their reported co-expression during development⁸, the cell-specific expression of the growth hormone and prolactin genes appears to be controlled by structurally distinct, cis-active sequences under regulation of discrete trans-acting factors. The

location of the prolactin gene enhancer described in this manuscript corresponds to a reported pituitary-specific pattern of chromosomal DNase I hypersensitivity, approximately 1.8 kb upstream of the CAP site¹¹. Because the prolactin *cis*-active sequence contains two separable regions which can be placed in either orientation with respect to each other and continue to functionally complement, we suggest that two (or more) *trans*-acting factors are required for the prolactin gene enhancer function in lactotrophs. Exonuclease protection assays of the prolactin enhancer region following binding of extracts from

GH cells tentatively identify at least two distinct and specific protein binding regions coincident with those defined by the mapping analyses.

Although the enhancer sequence of the growth hormone gene contains a region (at -190 bp) which corresponds to the 'core' enhancer sequences identified in the immunoglobulin and several viral genes¹²⁻¹⁴, the growth hormone enhancer core sequence alone is insufficient for function because a region containing >40 bp on each side of this sequence exhibits no enhancer activity. Preliminary footprint analysis reveals that one region located 3' in the growth hormone gene enhancer specifically binds a factor in cells which express the gene (GH cells) but not in cells (235-1) in which the growth hormone enhancer fails to function.

Further understanding of the molecular basis for the selective activation or/and silencing of growth hormone or prolactin gene expression in the development of mature somatotrophs and lactotrophs will require analysis of the expression of transcription units containing heterologous promoters and the respective enhancer sequences in transgenic animals, and the identification and characterization of the cognate trans-acting factors.

We thank Charles Nelson for maintaining the cell culture requirements of the project, Drs John Porter and Michael Cronin for the 235-1 cell line, and Drs Patty Hinkle and Benita Katzenellenbogen for characterized cell lines. Transcriptional interference and termination between duplicated α -globin gene constructs suggests a novel mechanism for gene regulation

N. J. Proudfoot

Sir William Dunn School of Pathology, University of Oxford, South Parks Road, Oxford OX1 3RE, UK

The interesting possibility that transcriptional interference can occur between eukaryotic genes was raised by studies on the avian leukosis retrovirus (ALV)1 which showed that deletion of the promoter in the 5' long terminal repeat (LTR) activates the 3' LTR promoter, linked to a downstream gene. These observations provide a molecular explanation for the fact that insertional oncogenesis by the ALV promoter is invariably associated with either a rearranged or deleted 5' LTR sequence2-4. This letter extends these findings to chromosomal RNA polymerase II genes by studying transcriptional interference between duplicated α globin gene constructions. I demonstrate that transcriptional interference causes substantial inhibition of the downstream α gene by transcription of the upstream α gene. Furthermore, this inhibition is alleviated by placing transcriptional termination signals between the two α genes. Because many eukaryotic genes may be arranged in tandem on a chromosome, these observations suggest that transcriptional termination is an important mechanism for preventing interference between adjacent genes. The selective use of termination signals may provide a novel way of regulating the activity of eukaryotic genes.

The HeLa cell transient expression procedure^{5,6} was used initially as a convenient system to study α -globin gene transcription. In this technique, the a genes are introduced into HeLa cells as part of an episomal plasmid that may be present at copy numbers as high as 10,000 or more per cell nucleus⁶. Figure 1a shows a diagram of the pSVod plasmid⁶ containing two human α -globin genes ($\alpha\alpha$ pSVod). The α genes are separated by about 700 base pairs (bp) and each one contains more than 300 bp of 5'-flanking sequences but only about 100 bp of 3'-flanking

sequence. Therefore, although the poly(A) sites of each α gene are intact, they are unlikely to contain possible 3'-flanking region termination signals. pSVod is a transient expression vector based on pBR322 containing the simian virus 40 (SV40) replication origin but not the enhancer sequence (72-bp repeat). The SV40 early and late promoters are also present in the SV40 origin (ori) region but will be largely inactive in pSVod, since the early promoter requires the enhancer^{7,8}, and the late promoter has its major initiation sites within the 72-bp repeat sequence, absent in pSVod9. Co-transfection of pSVod with another plasmid (SVpBR328Rβ1)¹⁰ containing both the SV40 large-T antigen and rabbit β -globin genes allows replication of SV40 origincontaining plasmids⁵ as well as providing a control to test for efficiency of transfection. The 5' α -globin gene has a 13-bp insert in its 5' noncoding sequence, called Tag, to allow the otherwise identical 5' termini of the two α -gene transcripts to be distinguished by the primer extension RNA mapping technique¹¹. Figure 1a also shows two constructs in which either the 5' α -gene or 3' α -gene promoter is deleted ($\Delta P \alpha \alpha$ and $\alpha \Delta P \alpha$).

Figure 1b shows the primer extension analysis on $\alpha\alpha$, $\Delta P\alpha\alpha$ and $\alpha \Delta P \alpha$ transfections. The relative efficiency of each transfection is indicated by the intensity of the 3'-end signal produced by S_1 nuclease mapping¹² of rabbit β -globin messenger RNA in turn produced by the co-transfected plasmid shown under each lane. RNA from cells transfected with $\alpha\alpha$ pSVod gives two extension products corresponding to the Tag-containing 5' α gene mRNA and normal 3' α -gene mRNA. The product bands are doublets, as is usually observed with primer extension, possibly reflecting partial extension onto the 5' CAP structure of the mRNA. Deletion of the promoter of the 5' α gene as shown by $\Delta P \alpha \alpha$ results in an approximately threefold increase in the 3' α -gene signal. Surprisingly, deletion of the promoter of the 3' α gene also results in an approximately threefold increase in the 5' α -gene signal as can be seen by comparing $\alpha\alpha$ and $\alpha\Delta P\alpha$. These data indicate that each α -gene promoter exerts an inhibitory effect on the other α -gene promoter. One possible cause of this inhibition could be through a competitive effect between the two α -gene promoters for possibly limiting factors. Alternatively, a transcriptional interference mechanism may be responsible for the observed modulation in mRNA levels.

b

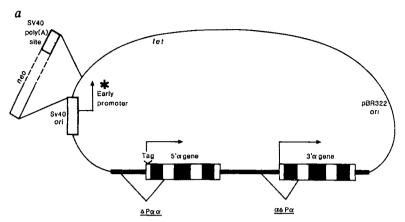

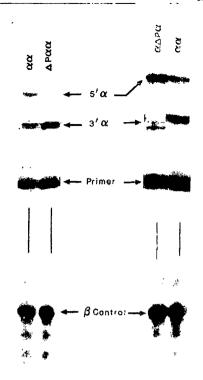

Fig. 1 a, Diagram of $\alpha\alpha$ pSVod (ref. 6). α Genes are depicted by a thick line for flanking sequences, open boxes for noncoding and intron sequences, solid boxes for exon sequences. The positions of the promoter deletions in $\Delta P\alpha\alpha$ and $\alpha\Delta P\alpha$ are indicated. \Box Denotes position and direction of promoter. * Indicates that the SV40 early promoter is only functional in pSVedneo. The pBR322 sequence is depicted by a thin line. Note that the sequence in pBR322 found to inhibit SV40 replication (between the pBR322 replication origin and tetracycline resistance gene (tet^r) gene) is deleted in pSVod. SV40 sequences are depicted by shaded boxes. The SV40 ori sequence in pSVod contains the replication origin but not the enhancer. As indicated, the neomycin resistance gene and SV40 poly(A) site¹⁷ were added to the plasmid. In addition, the SV40 origin region was expanded slightly to include the enhancer sequence as this is required for the early promoter^{7,8}. b, Primer extension RNA analysis¹¹ on cytoplasmic RNA purified from HeLa cells transiently transfected with $\alpha\alpha$ -; $\Delta P\alpha\alpha$ - and $\alpha\Delta P\alpha$ SVod, together with the co-transfection control plasmid SVpBR328R β 1 (ref. 10). 3'-End S₁ mapping 12 data on rabbit β -globin mRNA produced by SVpBR328R β 1 are shown beneath each lane.

Methods. DNA constructions: The Tag α promoter was constructed by ligating a 134-bp human α 1-globin gene HinfI fragment containing 112 bp of 5'-flanking sequence together with 22 bp of 5' noncoding sequence into the polylinker Sall site of pUC9²³ This Hinfl fragment contained all the sequence required for initiation of transcription of the α 1-globin gene promoter. Next, an 894-bp Hinfl-Pul fragment containing the rest of the α 1-globin gene was ligated into the BamHI site of pUC9, next to the previously used Sall site. This effectively results in expansion of the 5' noncoding Hinfl site of the α 1-globin gene by 13 nucleotides and thereby 'Tags' the 5' end of the α 1 gene²³. $\alpha\alpha$ -, $\Delta P \alpha \alpha$ - and $\alpha \Delta P \alpha p S V$ od were made by cutting α 1pSVod with Smal to remove the promoter region and exon 1 of α 1. Tag α pSVod was then made by ligating the same Smal fragment from Tag alpUC9 into the Sma-cut alpSVod vector. APapSVod was made by ligating alpSVod Sma vector back together without an insent fragment The second al gene as a 1.6-kb PstI fragment was then added to Tag or APalpSVod at a unique PstI site in the 3'-flanking sequence of the a gene to make ααpSVod and ΔΡααpSVod. Similarly, a ΔΡα1 gene fragment was added 3' to Tag α1pSVod to make αΔΡαpSVod. pSVedneo: The plasmid pSV2*neo containing the Tn5 neomycin phosphotransferase gene which contains the SV40 early promoter and poly(A) site flanking the neo gene has been described elsewhere HindIII-BamHI fragment containing the neo gene and the SV40 early poly(A) site from pSV2*neo was ligated into pSVed between the HindIII and BamHI sites pSVed is a variant on pSVod containing slightly more SV40 origin sequence to include the transcriptional enhancer²⁴. Various α-gene-containing pSVod plasmids were then converted into pSVedneo plasmids by exchanging the EcoRI-BamHI fragment in pSVod for the equivalent SV40 origin neo fragment in pSVedneo HeLa cell translent expression: Transfections were carried out as described previously^{6,24}. Briefly plasmid DNA was precipitated with calcium phosphate and added to subconfluent Petri dishes of HeLa cells. After 10-16 h, the medium was changed and the cells allowed to grow for another 48 h. The HeLa cells were collected, lysed in Nonidet P-40 detergent buffer, and the cytoplasmic and nuclear fractions separated by centrifugation through a sucrose cushion. Following incubation with proteinase K, cytoplasmic RNA was purified by phenol chloroform extraction and ethanol precipitation. RNA mapping: Primer extension11 DNA primer for α -globin mRNA 5'-end analysis was a single-strand HinfI-HaeIII fragment extending from the middle of the first exon to the middle of the 5'-noncoding region of the α 1-globin gene. This was obtained by filling in the HinfI end of the double-strand DNA with $[\alpha^{-3^2}P]$ dATP and fractionating on α denaturing 7 M urea 12% polyacrylamide gel. DNA primer (20 c.p.m., specific activity 3,000 Ci mmol⁻¹) and cytoplasmic RNA (~20 µg) were annealed in 10 µl of 10 mM PIPES pH 6.4, 0.4 M NaCl at 80 °C for 10 min and at 63 °C overnight. 50 µl of reverse transcriptase buffer (50 mM Tris pH 8.2, 10 mM duthiothicuol. 6 mM MgCl₂, 0.5 mM dATP, dCTP, dTTP and dGTP plus reverse transcriptase (5 U)) were added to hybridizations and incubated at 42 °C for 1 h. RNave (20 µg) was added to incubation and left a further 15 min at 42 °C. The reaction was phenol extracted, ethanol precipitated and fractionated by electrophoresis on 7 M urea polyacrylamide gels. S_1 mapping 12 : SVpBR328R β 1 was digested with EcoRI and the ends filled in with $[\alpha^{-32}P]$ dATP using standard procedures. This gives urea polyacytamine gets. 5₁ mapping: Syphologory i was digested with Ecoki and the ends filled in with [α-T-P]dAIP using standard procedures. This gives a rabbit β-globin mRNA S₁ probe labelled at an EcoRi site at the beginning of the last exon. The 3'-end signal for rabbit β-globin mRNA is approximately 200 nucleotides. The S₁ probe (-20 c.p.m., specific activity 3,000 Ci mmol⁻¹) was annealed to HeLa cell cytoplasmic RNAs (-20 μg) in 30 μl of 80% formanide, 0.04 M PIPES pH 6.8, 0.4 M NaCl, 0.1 mM EDTA by denaturation at 80 °C for 10 min, then 53 °C overnight. Ice-cold S₁ buffer (0.3 ml; 0.25 M NaCl, 0.0) M NaOAc pH 4.6, 2 mM ZnSO₄, 50 μg ml⁻¹ denatured sonicated carrier DNA) plus S₁ (3,000 U) was quickly added to each hybridization and incubated for 1 h at 30 °C. S_I reactions were ethanol precipitated and fractionated on denaturing, 7 M urea polyacrylamide gels.

To test which of these two explanations is correct, I investigated the effect of placing RNA polymerase II termination signals between the two α genes. Two termination signals have been identified and characterized for RNA polymerase II genes, one for the sea urchin H2A histone gene^{13,14} and the other for the mouse β -globin gene^{15,16}. However, in both cases, it was necessary to include fairly extensive regions of sequence including both the 3' end of the gene as well as 3'-flanking sequence, since neither terminator signal has vet been localized more precisely. Figure 2a demonstrates the various positions in which these terminators were placed with respect to the duplicated α -globin genes. First, the histone terminator was positioned either between $(\alpha T\alpha)$ or after $(\alpha \alpha T)$ the two α genes. As a control, a deleted form of the histone terminator which is known to have lost its termination activity¹³ was placed between the two α genes ($\alpha\Delta T\alpha$). Second, the mouse β termination sequences were placed in both orientations between the two α genes $(\alpha \vec{m} \beta \alpha \text{ and } \alpha \vec{m} \beta \alpha).$

Figure 2b shows the primer extension data obtained for this second set of $\alpha\alpha$ pSVod constructs. No co-transfection controls are shown for these experiments, since each primer extension experiment is internally controlled by the ratios of the Tag α and α bands. As indicated, $\alpha T\alpha$ caused an approximately threefold increase in the 3' α - as compared with the 5' α -gene signal while $\alpha\alpha T$ caused a similar threefold increase in the 5' α -gene signal. Thus, placing a terminator sequence between or after the duplicated α genes has a similar effect to deleting either of the two α -gene promoters. The control $\alpha\Delta T\alpha$ with a nonfunctional termination signal¹³ gave more equal ratios of 5' and 3' α signals, demonstrating that the 3:1 ratio for 5' α to 3' α in $\alpha T\alpha$ is caused by a termination process. In fact, the 5' α signal is routinely lower than the 3' α signal in $\alpha\alpha$ pSVod, possibly due to the Tag sequence which may reduce the efficiency of the α -gene promoter. Finally, $\alpha\vec{m}\beta\alpha$ gave threefold more 3' α signal

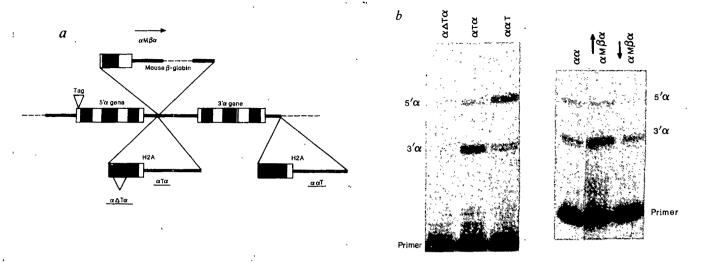

Fig. 2 a, Diagram showing positions of H2A histone and β -globin gene termination signals with respect to the two genes in $\alpha\alpha$ pSVod. The mouse β -globin terminator was placed in both orientations between the two α genes. The arrow denotes the normal direction of transcription on the β -globin gene. Key as for Fig. 1a. b, Primer extension RNA analysis on $\alpha\alpha$ pSVod terminator transfection as in Fig. 1.

Methods. DNA constructions: H2A histone terminator: A 0.9-kb TaqI fragment containing the 3' side of the sea urchin H2A histone gene together with nearly all of its 3'-flanking sequence was purified from a larger plasmid containing the whole gene (a generous gift from Professor M. Birnstiel, University of Zurich). This fragment has been shown to contain all of the necessary signals to elicit transcriptional termination (ref. 13). The histone H2A gene Taq fragment (T) was then added to either of the PatI sites flanking the 3' α 1-slobin gene $(\alpha T\alpha$ - and $\alpha\alpha$ TpSVod). Finally, α T α was cut with Sac I and PvuI to excise a region of the histone

fragment has been shown to contain all of the necessary signals to elicit transcriptional termination (ref. 13). The histone H2A gene Taq fragment (T) was then added to either of the PstI sites flanking the 3' α1-globin gene (αTα- and ααTpSVod). Finally, αTα was cut with SacI and PvuI to excise a region of the histone gene that is essential for transcriptional termination (ref. 13). Mouse β major globin terminator: An EcoRI-BgIII DNA fragment containing the whole mouse β-major globin gene plus extensive 3'-flanking sequence was subcloned into pSVed (ref. 24) between the EcoRI and HincII sites (amp gene): mβmajpSVed. A PstI fragment was then excised from mβmajpSVed which extended from the 3' end of intron 2 to the PstI site in pSVed 300 bp beyond the HincII site. This fragment contains the essential D, E and F fragments defined by Falck-Pedersen et al. 16 as well as 300 bp of pBR322 amp resistance gene sequence. The 2.0 kb PstI fragment was then ligated into the PstI site between the two α genes in ααpSVod in both orientations to form αmβα- and αmβαpSVod.

while $\alpha \tilde{m} \beta \alpha$ and $\alpha \alpha$ gave nearly equal levels of 5' and 3' α signal. These results confirm the data obtained for $\alpha T \alpha$ by demonstrating that a second terminator sequence, that from the mouse β -globin gene, behaves exactly as the histone terminator and, furthermore, that it is orientation specific. Taken together, these data argue that transcriptional interference does occur between the duplicated α genes, rather than a promoter competition effect. In fact, the data indicate that not only does the first α gene interfere with the second α gene, but also that the second α gene, presumably by transcription all around pSVod, in turn interferes with the first α gene. This would suggest that in $\alpha\alpha$ both α genes are subject to equal transcriptional interference. so that the two α gene signals are nearly equal. However, with $\alpha T \alpha$ the second α gene is released from interference but the first is not, resulting in a 1:3 ratio. Finally, with $\alpha\alpha T$, the first α gene, but not the second, is released from interference, giving a ratio of 3:1.

The present studies on the transcription of duplicated α genes in a transient expression assay demonstrate that a nearly threefold transcriptional interference effect occurs between the two adjacent α -globin genes. The observation that the 3'-positioned α gene inhibits the 5' α gene by transcription all the way around the plasmid suggests that transcriptional interference occurs over a distance of at least 3 kilobases (kb). In fact, this possibility is confirmed by the $\alpha m\beta \alpha pSVod$ constructs which effectively separate the two α -globin genes by 3 kb and yet clearly demonstrate a transcriptional interference effect between the two α globin genes (Fig. 2b). Clearly, the study of multiple genes in transient expression plasmids must take into account transcriptional interference as a possible cause of modulation in promoter efficiency. The molecular basis of this interference effect is probably due to RNA polymerase II molecules first transcribing the 5' gene and then reading on into the 3' gene. This effectively obscures the promoter of the 3' gene from independent initiation of transcription by other RNA polymerase II molecules. Transcriptional termination would thus alleviate this interference

effect. The observation that both the H2A and mouse β -globin terminator sequences prevent this interference effect is therefore strong confirmatory evidence that these sequences are transcriptional terminators.

The fact that I observe a threefold interference effect in transient expression may not reflect the true physiological levels of this phenomenon. In transient expression, as many as 10,000 copies of the plasmid are generated by replication. Thus, pSVod

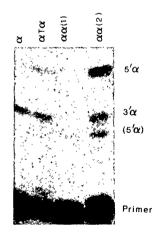

Fig. 3 Primer extension analysis on G418-resistant HeLa cell pools transfected with either $\alpha\alpha$ pSVedneo (two separate pools) or α T α pSVedneo. The α lane is a control experiment using RNA purified from the α -globin-producing cell line K562 (ref. 24).

Methods. The $\alpha\alpha$ - and α T α pSVedneo plasmids together with SVpBR328R β 1 as a source of large-T antigen were transfected onto HeLa cells as for Fig. 1. Following exposure to the calcium phosphate-DNA precipitates, the HeLa cells were incubated for 48 h and G418 (80 μ g⁻¹) was then added to the medium. After about 2 weeks of G418 selection, small, resistant colonies were obtained and allowed to grow to confluence. Primer extension assays were performed as for Fig. 1, but ~100 μ g of cytoplasmic RNA was used in each reaction to obtain detectable signals.
